warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Contributors List

Cynthia K. Aaron, MD, FACMT, FACEP
Program Director, Medical Toxicology
Regional Poison Center
Children’s Hospital of Michigan
Detroit, Michigan

Gregory A. Abrahamian, MD
Surgical Director of Kidney Transplantation
University Transplant Center
University of Texas Health Science Center, San Antonio
San Antonio, Texas

Konstantin Abramov, MD, MHL
Assistant Professor of Medicine
Division of Renal Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

Christopher D. Adams, PharmD
Clinical Assistant Professor
Department of Pharmacy
Robert Wood Johnson University at Somerset
Somerville, New Jersey

Sumera R. Ahmad, MD
Division of Pulmonary, Allergy and Critical Care
Department of Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

Alfred Aleguas, Jr, BS Pharm, PharmD, DABAT, FAACT
Managing Director
Florida Poison Information Center-Trauma
Tampa General Hospital
Tampa, Florida

Gilman B. Allen, MD
Associate Professor
Department of Medicine
Division of Pulmonary Medicine and Critical Care
University of Vermont Medical Center
Burlington, Vermont

Jennifer E. Allen, MD
Palliative Medicine Consultant
Department of Oacis Services
Lehigh Valley Health Network
Allentown, Pennsylvania

Diana C. Anderson, MD, MArch
Founder, Dochitect
Physician, American Board of Internal Medicine (ABIM)
Architect, American College of Healthcare Architects (ACHA)
Montreal, Quebec, Canada

Gustavo Guillermo Angaramo, MD
Associate Professor of Anesthesiology and Critical Care
Director of Perianesthesia Unit
Department of Anesthesiology and Perioperative Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

Luis F. Angel, MD
Professor, Department of Medicine
Professor, Department of Cardiothoracic Surgery
Medical Director, Lung Transplantation
NYU Langone Health
New York

Kevin E. Anger, PharmD
Pharmacy Supervisor
Department of Pharmacy
Brigham and Women’s Hospital
Boston, Massachusetts

Derek C. Angus, MD
Distinguished Professor and Mitchell P. Fink Endowed Chair
Department of Critical Care Medicine
University of Pittsburg School of Medicine
Pittsburgh, Pennsylvania

Robert Arntfield, MD
Associate Professor of Critical Care
Western University
Department of Critical Care
London Health Sciences Centre
London, Ontario

Neil Aronin, MD
Chief, Division of Endocrinology
Professor, University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, Massachusetts

Seth M. Arum, MD
Clinical Associate Professor of Medicine
Department of Medicine/Endocrinology
UMass Memorial Medical Center
Worcester, Massachusetts

Assistant Professor
Division of Endocrinology Metabolism and Diabetes
University of Massachusetts Medical School
Worcester, Massachusetts

Richard T. Ellison, III, MD
Hospital Epidemiologist
Professor of Medicine, Microbiology and Physiological Systems
University of Massachusetts Medical School
Department of Medicine
Division of Infectious Diseases
UMass Memorial Medical Center
Worcester, Massachusetts

Ashkan Emadi, MD, PhD
Associate Professor of Medicine, Pharmacology and Experimental Therapeutics
Director, Hematology & Medical Oncology Fellowship
Department of Medicine, Hematology/Medical Oncology
University of Maryland School of Medicine
Marlene & Stewart Greenebaum Comprehensive Cancer Center
Baltimore, Maryland

Charles H. Emerson, MD
Professor Emeritus of Medicine
Division of Endocrinology and Metabolism
University of Massachusetts Medical School
Worcester, Massachusetts

Timothy A. Emhoff, MD, FACS
Chief Trauma and Surgical Critical Care
Department of Surgery
UMass Memorial Medical Center
Worcester, Massachusetts

Jennifer L. Englund, MD
Emergency Medicine Physician
Maplewood, Minnesota

Robert M. Esterl, Jr, MD
Professor of Surgery
Department of Surgery
The University of Texas Health Science Center at San Antonio
San Antonio, Texas

Julien Fahed, MD
Resident
Department of Internal Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

Pang-Yen Fan, MD
Professor of Medicine
Department of Medicine
University of Massachusetts Medical School
Worcester, Massachusetts
James C. Fang, MD
Adjunct Professor
Department of Medicine
Case Western Reserve University School of Medicine
Cleveland, Ohio

John Fanikos, BS, MBA
Director of Pharmacy
Department of Pharmacy
Brigham and Women’s Hospital
Boston, Massachusetts

Harrison W. Farber, MD
Professor of Medicine
Director, Pulmonary Hypertension Center
Boston University
Boston Medical Center
Boston, Massachusetts

Khaldoun Faris, MD
Clinical Associate Professor
Director, Anesthesiology CCM
Department of Anesthesiology
University of Massachusetts Medical School
Worcester, Massachusetts

Alan P. Farwell, MD
Chief, Section of Endocrinology, Diabetes and Nutrition
Department of Medicine
Boston Medical Center/Boston University
Boston, Massachusetts

Alan M. Fein, MD
Clinical Professor of Medicine
Department of Pulmonary and Critical Care
Hofstra Northwell School of Medicine
Lake Success, New York

Stacey Feinstein, DO, MBA
Emergency Physician
Department of Emergency
Memorial Hospital Pembroke
Pembroke Pines, Florida
Sean Figy, MD  
Resident Physician  
Division of Plastics and Reconstructive Surgery  
Department of Surgery  
University of Massachusetts Medical School  
Worcester, Massachusetts

Robert W. Finberg, MD  
Richard M. Haidack Professor Medicine  
Professor, Microbiology & Physiological Systems  
Chair, Department of Medicine  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts

Kimberly A. Fisher, MD  
Assistant Professor  
Department of Medicine  
Division of Pulmonary and Critical Care  
University of Massachusetts Medical Center  
Worcester, Massachusetts

Christina Fitch, DO, MPH  
Assistant Professor  
Department of Palliative Care  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts

Avegail G. Flores, MD  
Assistant Professor, Hepatology Program  
Division of Gastroenterology  
Department of Medicine  
Washington University  
St. Louis, Missouri

Dee W. Ford, MD, MSCR  
Associate Professor of Medicine  
Department of Pulmonary and Critical Care Medicine  
Medical University of South Carolina  
Charleston, South Carolina

Marsha D. Ford, MD
Loma Linda University
Loma Linda, California

**Christos Galatas, MD**  
Cardiology Fellow  
Department of Cardiology  
McGill University  
Montreal, Quebec, Canada

**Sumanth Gandra, MD, MPH**  
Resident Scholar  
The Center For Disease Dynamics, Economics & Policy  
New Dehli, India

**Javier Barreda Garcia, MD**  
Assistant Professor  
Department of Internal Medicine  
Division of Pulmonary and Critical Care Medicine  
The University of Texas Health Science Center at Houston  
Houston, Texas

**Anne Garrison, MD**  
Director Obstetrics-Gynecology Clerkship  
Assistant Professor  
University of Massachusetts Medical School  
UMass Memorial Medical Center - Memorial Campus  
Worcester, Massachusetts

**James Geiling, MD, MPH**  
Professor of Medicine, Geisel School of Medicine at Dartmouth  
Veterans Affairs Medical Center  
White River Junction, Vermont

**Edith S. Geringer, MD**  
Boston, Massachusetts

**Terry Gernsheimer, MD**  
Professor of Medicine  
Division of Hematology  
Medical Director of Transfusion  
Seattle Cancer Care Alliance  
University of Washington  
Seattle, Washington
Hayley B. Gershengorn, MD  
Assistant Professor  
Department of Medicine  
Albert Einstein College of Medicine  
Montefiore Medical Center  
Bronx, New York

Michael M. Givertz, MD  
Medical Director, Heart Transplant and Mechanical Circulation Support  
Brigham and Women’s Hospital  
Professor of Medicine  
Harvard Medical School  
Boston, Massachusetts

Richard H. Glew, MD  
Professor of Medicine and Microbiology and Physiological Systems  
Department of Medicine/Infectious Diseases  
UMass Memorial Medical Center  
Worcester, Massachusetts

Richard P. Goddeau, Jr, DO, FAHA  
Associate Professor of Neurology  
Department of Neurology  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts

Dori Goldberg, MD  
Assistant Professor  
Division of Dermatology  
University of Massachusetts Medical School  
Worcester, Massachusetts

Andrew J. Goodwin, MD, MSCR  
Assistant Professor  
Division of Pulmonary, Critical Care, Allergy and Sleep Medicine  
Medical University of South Carolina  
Charleston, South Carolina

Susan E. Gorman, MD  
Associate Director for Science  
Division of Strategic National Stockpile  
Centers for Disease Control and Prevention
Bethesda, Maryland

**Andis Graudins, MBBS (Hons), PhD, FACEM, FCMT**
Professor of Emergency Medicine and Toxicology Research
School of Clinical Sciences at Monash Health, Monash University
Director, Clinical Toxicology Services
Monash Toxicology, Emergency Medicine Program,
Monash Health
Dandenong Hospital
Dandenong, Victoria, Australia

**Gay Graves, MS, RD/LDN**
Nutrition Support Dietitian
Department of Center for Human Nutrition
Vanderbilt University Hospital
Center for Human Nutrition
Nashville, Tennessee

**Damian J. Green, MD**
Assistant Member and Assistant Professor of Medicine
Clinical Research Division
Fred Hutchinson Cancer Research Center
University of Washington
Seattle, Washington

**Bruce Greenberg, MD**
Assistant Professor
Department of Medicine
Assistant Director
UMass Memorial Medical Center
Division of Pulmonary, Allergy and Critical Care
University of Massachusetts Medical School
Worcester, Massachusetts

**Thomas C. Greenough, MD**
Associate Professor
Department of Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

**Bonnie C. Greenwood, PharmD, BCPS**
Clinical Program Director
Department of Clinical Pharmacy Services
University of Massachusetts Medical School
Shrewsbury, Massachusetts

**Peeyush Grover, MD**
Cardiology Fellow
Department of Cardiology
UMass Memorial Medical Center
Worcester, Massachusetts

**Rainer W. G. Gruessner, MD, FACS, FICS**
Professor of Surgery
Chief of Transplantation
Department of Surgery and Transplant Services
SUNY Upstate Medical University
Syracuse, New York

**C. Prakash Gyawali, MD**
Professor of Medicine
Division of Gastroenterology
Barnes Jewish Hospital
Washington University in St. Louis
St. Louis, Missouri

**Michelle K. Haas, MD**
Assistant Professor of Medicine
Division of Infectious Diseases
University of Colorado Health Science Center
Denver Public Health and Hospital Authority
Denver, Colorado

**Shirin Haddady, MD, MPH**
Clinical Assistant Professor
Department of Internal Medicine
Division of Endocrinology
Boston Medical Center
Boston University School of Medicine
Boston, Massachusetts

**Wiley R. Hall, MD**
Director of Neurocritical Care
UMass Memorial Medical Center
Worcester, Massachusetts

**Hurst M. Hall, MD**
Assistant Professor
Department of Medicine
Division of Cardiology
UT Southwestern Medical Center
Dallas, Texas

**Neil A. Halpern, MD, MCCM, FACP, FCCP**
Professor of Clinical Medicine
Professor of Medicine and Clinical Anesthesiology
Weill Cornell Medical College
Director, Critical Care Center
Chief, Critical Care Medicine Service
Department of Anesthesiology and Critical Care Medicine
Memorial Sloan Kettering Cancer Center
New York, New York

**Tarek Abou Hamdan, MD**
Gastroenterology and Interventional Endoscopy Consultant
Division of Gastroenterology
Clemenceau Medical Center Affiliated with Johns Hopkins International
Beirut, Lebanon

**Samuel Y. Han, MD**
Fellow
Department of Gastroenterology
University of Colorado
Aurora, Colorado

**Stephen B. Hanauer, MD**
Professor
Department of Medicine (Gastroenterology, Hepatology)
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Sundaram Hariharan, MD**
Professor of Medicine and Surgery
Robert J. Corry Chair of Surgery
Department of Medicine and Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

**David M. Harlan, MD**
William and Doris Krupp Professor of Medicine
Co-Director, Diabetes Center of Excellence
Department of Medicine
Division of Diabetes
UMass Memorial Medical Center
Worcester, Massachusetts

**Laura Harrell Raffals, MD, MS**
Associate Professor of Medicine
Section of Gastroenterology and Hepatology
Mayo Clinic
Rochester, Minnesota

**Steven Hatch, MD, MS**
Associate Professor of Medicine
Division of Infectious Diseases
University of Massachusetts Medical School
Worcester, Massachusetts

**Ashley Haynes, MD**
Assistant Professor
Department of Emergency Medicine
Division of Medical Toxicology
University of Texas Southwestern
Parkland Health and Hospital System
Dallas, Texas

**Lawrence J. Hayward, MD**
Professor of Neurology
Department of Neurology
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, Massachusetts

**Stephen O. Heard, MD**
Professor of Anesthesiology and Surgery
Department of Anesthesiology and Perioperative Medicine
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, Massachusetts

**Kennon Heard, MD**
Professor of Emergency Medicine
Department of Emergency Medicine
University of Colorado School of Medicine
Aurora, Colorado
Benedikt H. Heidinger, MD
Research Fellow
Department of Radiology
Harvard Medical School
Beth Israel Deaconess Medical Center
330 Brookline Avenue
Boston, Massachusetts

Vitaly Herasevich, MD, PhD, FCCM
Associate Professor of Anesthesiology and Medicine
Department of Anesthesiology
Mayo Clinic
Rochester, Minnesota

Daniel Hetherman, MD
Resident
Department of Surgery
University of Massachusetts Medical School
Worcester, Massachusetts

Thomas L. Higgins, MD, MBA, FACP, MCCM
Chief Medical Officer and Interim President and CEO
Baystate Franklin Medical Center
Greenfield, Massachusetts
Professor of Medicine and Surgery and Anesthesiology
Tufts University School of Medicine
Boston, Massachusetts

Nicholas S. Hill, MD
Chief
Department of Pulmonary, Critical Care and Sleep Division
Tufts Medical Center
Boston, Massachusetts

John B. Holcomb, MD, FACS
Professor and Vice Chair
Department of Surgery
Memorial Hermann Hospital
Houston, Texas

Judd E. Hollander, MD
Associate Dean for Strategic Health Initiatives
Vice Chair for Finance and Healthcare Enterprises
Department of Emergency Medicine
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

**Helen M. Hollingsworth, MD**
Associate Professor of Medicine
Boston University School of Medicine
Boston Medical Center
Department of Pulmonary Allergy and Critical Care Medicine
UpToDate—Wolters Kluwer Health
Waltham, Massachusetts

**Shelley A. Holmer, MD**
Psychiatrist
Duke Health
Durham, North Carolina

**Jonathan E. Holtz, MD**
Clinical Instructor
Advanced Heart Failure Cardiologist
Department of Medicine
University of Pittsburgh Medical Center
Altoona, Pennsylvania

**Donough Howard, MD**
Consultant Rheumatologist
Hermitage Medical Clinic
Dublin, Ireland

**Michael D. Howell, MD, MPH**
Chief Quality Officer
Director, Center for Healthcare Delivery Science and Innovation
University of Chicago Medicine
Chicago, Illinois

**Misha Huang, MD**
Attending Physician
Denver Veterans Affairs Medical Center
Instructor
Department of Infectious Diseases
University of Colorado
Aurora, Colorado

**Rolf D. Hubmayr, MD**
Professor of Medicine and Physiology
Department of Pulmonary and Critical Care
Mayo Clinic
St. Louis Park, Minnesota

**John Terrill Huggins, MD**
Associate Professor
Department of Medicine
Division of Pulmonary and Critical Care
Medical University of South Carolina
Charleston, South Carolina

**Abhinav Humar, MD**
Thomas E. Starzl Professor in Transplantation Surgery
Clinical Director, Thomas E. Starzl Transplantation Institute
Chief, Division of Transplant Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

**Benjamin Hyatt, MD**
Assistant Professor of Medicine
Division of Gastroenterology
UMass Memorial Medical Center
Worcester, Massachusetts

**Richard S. Irwin, MD, Master FCCP**
Professor of Medicine and Nursing
University of Massachusetts Medical School
Chair, Critical Care Operations
UMass Memorial Medical Center
Worcester, Massachusetts

**Margaret Isaac, MD**
Adult Medicine Clinic and Palliative Care Service
Harborview Medical Center
Assistant Professor
University of Washington School of Medicine
Seattle, Washington

**Janetta L. Iwanicki, MD**
Assistant Professor, Emergency Medicine and Medical Toxicology
Department of Emergency Medicine
Denver Health and Hospital Authority
University of Colorado School of Medicine
Denver, Colorado

Colleen L. Jay, MD, MS
Assistant Professor of Surgery
University Transplant Center
University of Texas Health Science Center, San Antonio
San Antonio, Texas

Donald H. Jenkins, MD, FACS
Professor/Clinical
Division of Trauma and Emergency Surgery
Vice Chair for Quality
Department of Surgery
Betty and Bob Kelso Distinguished Chair in Burn and Trauma Surgery
Associate Deputy Director
Military Health Institute
University of Texas Health Science Center, San Antonio
San Antonio, Texas

Thanjira Jiranantakan, MD, MPH
Lecturer, Medical Toxicologist
Department of Preventive and Social Medicine
Division of Toxicology, Occupational & Environmental Medicine
Faculty of Medicine Siriraj Hospital
Mahidol University
Medical Toxicology
Attending Physician
Siriraj Poison Control Center
Bangkok Noi, Bangkok

Scott B. Johnson, MD
Chief of General Thoracic Surgery
Department of Cardiothoracic Surgery
University of Texas Health Science Center at San Antonio
San Antonio, Texas

Dejah R. Judelson, MD
Resident
Division of Vascular Surgery
UMass Memorial Medical Center
Worcester, Massachusetts
Bryan S. Judge, MD
Associate Professor
Department of Emergency Medicine
Spectrum Health
Grand Rapids Medical Education Partners/Michigan State University
College of Human Medicine Program in Emergency Medicine
Grand Rapids, Michigan

Firas Kaddouh, MD
Neurology Resident
Department of Neurology
UMass Memorial Medical Center
Worcester, Massachusetts

Marc J. Kahn, MD, MBA, FACP
Peterman-Prosser Professor
Senior Associate Dean
Departments of Medicine and Pharmacology
Division of Hematology/Medical Oncology
Tulane University School of Medicine
Office of Admissions and Student Affairs
New Orleans, Louisiana

Biren B. Kamdar, MD, MBA, MHS
Assistant Professor
Division of Pulmonary and Critical Care Medicine
David Geffen School of Medicine at University of California
Los Angeles, California

Padmanaidu Karnam, MD
Rheumatology Fellow
Department of Rheumatology
UMass Memorial Medical Center
Worcester, Massachusetts

Sheetal Karne, MD
Hematology Oncology Fellow
Marlene and Stewart Greenebaum Cancer Center
University of Maryland
School of Medicine
Baltimore, Maryland
Jason N. Katz, MD, MHS
Associate Professor of Medicine
Department of Medicine
Division of Cardiology and Pulmonary & Critical Care Medicine
Medical Director, UNV Mechanical Heart Program
Medical Director, Cardiac Intensive Care Unit
Medical Director, Cardiothoracic Surgical Intensive Care Unit & Critical Care Service
Director, Cardiovascular Clinical Trials
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Carol A. Kauffman, MD
Professor, Department of Internal Medicine
Chief, Division of Infectious Diseases
Veterans Affairs Ann Arbor Healthcare System
University of Michigan Medical School
Ann Arbor, Michigan

Andrew M. King, MD
Assistant Professor
Department of Emergency Medicine
Wayne State University School of Medicine
Detroit Medical Center
Detroit, Michigan

Mary A. King, MD, MPH
Pediatric Critical Care Medicine
Medical Director, PICU
Harborview Medical Center
Associate Professor
University of Washington
Seattle, Washington

Mark A. Kirk, MD
Associate Professor
Department, Emergency Medicine
UVA Health System
Charlottesville, Virginia

Karen M. Knops, MD
Medical Director, Palliative Care Program
Department of Palliative Care
Overlake Medical Center
Bellevue, Washington

**Meghan S. Kolodziej, MD**
Instructor in Psychiatry
Department of Psychiatry
Brigham and Women’s Hospital
Boston, Massachusetts

**Scott E. Kopec, MD**
Associate Professor
Department of Medicine
Division of Pulmonary, Allergy and Critical Care
University of Massachusetts Medicine School
Worcester, Massachusetts

**Pierre Kory, MD**
Chief Critical Care Service
Medical Director, Trauma and Life Support Center
Department of Medicine
University of Wisconsin Hospital and Clinics
Madison, Wisconsin

**Stephen J. Krinzman, MD**
Clinical Associate Professor Medicine
University of Massachusetts Medical School
Division of Pulmonary and Critical Care
Department of Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

**Jason M. Kurland, MD**
Assistant Professor of Medicine
Division of Renal Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

**Jennifer LaFemina, MD, FACS**
Assistant Professor of Surgery
Department of Surgery
Division of Surgical Oncology
University of Massachusetts Medical School
Worcester, Massachusetts
Laura A. Lambert, MD
Associate Professor
Department of Surgery
Divisions of Surgical Oncology and Palliative Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

Anthony J. Lembo, MD
Associate Professor of Medicine
Department of Medicine
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Adam B. Lerner, MD
Director, West Campus Clinical Operations
Department of Anesthesiology and Critical Care
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Stephanie M. Levine, MD
Professor of Medicine
Department of Medicine
Division of Pulmonary Diseases and Critical Care
University of Texas Health Center, San Antonio
San Antonio, Texas

William J. Lewander, MD
Vice Chair Pediatric Emergency Medicine
Department of Emergency
Hasbro Children’s Hospital
Providence, Rhode Island

Daniel H. Libraty, MD
Professor of Medicine
Department of Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

Craig M. Lilly, MD, FCCP
Professor of Medicine,
Anesthesiology, and Surgery
University of Massachusetts Medical School
Vice Chair, Critical Care Operations
Director, Tele-ICU Program  
UMass Memorial Medical Center  
Worcester, Massachusetts

**Christopher H. Linden, MD**  
Professor  
Division of Medical Toxicology  
Department of Emergency Medicine  
UMass Medical School  
Department of Emergency Services  
Milford Regional Medical Center  
Milford, Massachusetts

**Mark S. Link, MD**  
Professor of Medicine  
Department of Cardiology  
UT Southwestern Medical Center  
Dallas, Texas

**Carol F. Lippa, MD**  
Professor and Interim Chair  
Department of Neurology  
Drexel University College of Medicine  
Philadelphia, Pennsylvania

**Mauricio Lisker-Melman, MD**  
Professor of Medicine  
Director of Hepatology  
Department of Gastroenterology & Hepatology  
Washington University School of Medicine  
Barnes Jewish Hospital  
St. Louis, Missouri

**Diana E. Litmanovich, MD**  
Staff Radiologist, Cardiothoracic Imaging, BIDMC  
Director, Cardiac Imaging  
Director, Cardiothoracic Imaging Fellowship Program  
Associate Professor of Radiology  
Harvard Medical School  
Boston, Massachusetts

**Norman Scott Litofsky, MD**  
Professor and Chief, Director of Radiosurgery and Neuro-Oncology  
Division of Neurological Surgery
Afroza Liton, MD
Attending Physician
Department of Internal Medicine
St. Peters Hospital
Albany, New York

Frederic F. Little, MD
Assistant Professor of Medicine
Program Director, Allergy/Immunology Fellowship
Medical Director, Pulmonary, Allergy and Sleep Clinics
Department of Medicine
Boston University School of Medicine
Boston Medical Center
Boston, Massachusetts

Nancy Y. N. Liu, MD
Clinical Associate Professor
Department of Rheumatology
University of Massachusetts Medical School
UMass Memorial Medical Center-Memorial Campus
Worcester, Massachusetts

Melanie R. Loberman, MD
Instructor in Anaesthesia
Harvard Medical School
Department of Anesthesia, Critical Care & Pain Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Dana Lustbader, MD
Professor of Medicine
Chair, Department of Palliative Care
Hofstra Northwell School of Medicine
ProHEALTH Care, an Optum Company
Lake Success, New York

Alice D. Ma, MD
Professor of Medicine
Department of Hematology/Oncology
University of North Carolina
Chapel Hill, North Carolina
J. Mark Madison, MD  
Professor of Medicine and Microbiology and Physiological Systems  
Chief, Division of Pulmonary, Allergy and Critical Care Medicine  
Department of Medicine  
UMass Memorial Medical Center  
University of Massachusetts Medical School  
Worcester, Massachusetts

Garbo Mak, MD  
Assistant Professor  
Division of Critical Care, Pulmonary and Sleep Medicine  
University of Texas Health Science Center at Houston, Houston, Texas

Suzana K. E. Makowski, MD, MMM  
Co-Chief, Division of Palliative Care  
Department of Medicine  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts

Atul Malhotra, MD  
Professor  
Department of Medicine  
University of California San Diego  
La Jolla, California

Samir Malkani, MD, MRCP (UK)  
Clinical Professor of Medicine  
University of Massachusetts Medical School  
Diabetes Center of Excellence  
Worcester, Massachusetts

Mary E. Maloney, MD  
Chair, Division of Dermatology  
University of Massachusetts Medical School  
Worcester, Massachusetts

Max Mandelbaum, MD, PhD  
Resident  
Department of Neurology  
UMass Memorial Medical Center
Worcester, Massachusetts

Paul E. Marik, MD, FCCM
Chief, Pulmonary and Critical Care Medicine
Department of Medicine
Eastern Virginia Medical School
Sentara Norfolk General Hospital
Norfolk, Virginia

William L. Marshall, MD
Associate Professor
Department of Medicine
Division of Infectious Diseases
University of Massachusetts Medical School
Worcester, Massachusetts

Carlos Martinez-Balzano, MD
Assistant Professor of Medicine
Division of Pulmonary, Critical Care and Sleep
SUNY Upstate Medical University
Syracuse, New York

Paulo Martins, MD, PhD
Assistant Professor
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, Massachusetts

Christina Massey, MA
Predoctoral Intern
Department of Psychiatry
Massachusetts General Hospital
Boston, Massachusetts

Ryan C. Maves, MD, FACP, FIDSA
Attending Physician
Associate Professor of Medicine
Department of Infectious Disease and Critical Care Medicine
Uniformed Services University
San Diego, California

Paul H. Mayo, MD, FCCP
Academic Director Critical Care
Division of Pulmonary, Critical Care, and Sleep Medicine
Guy Maytal, MD
Medical Director, Ambulatory Psychiatry
Department of Psychiatry
Massachusetts General Hospital
Boston, Massachusetts

Melanie Maytin, MD
Instructor in Medicine
Division of Cardiovascular Medicine
Brigham and Women’s Hospital
Boston, Massachusetts

Joyce K. McIntyre, MD
Assistant Professor of Surgery, Pediatrics and Neurosurgery
Departments of Surgery, Pediatrics and Neurosurgery
Division of Plastics and Reconstructive Surgery
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, Massachusetts

Brandy McKelvy, MD
Associate Professor
Department of Internal Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
Memorial Herman Hospital Texas Medical Center
Lyndon B. Johnson General Hospital
University of Texas Health Science Center at Houston
Houston, Texas

Lloyd C. Meeks, MD
Intensivist, Regional Medical Director
Advanced ICU Care
St. Louis, Missouri

Brendan Merchant, MD
Fellow, Cardiovascular Medicine
Division of Cardiology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, Massachusetts

Marco Mielcarek, MD
Associate Professor of Medicine/Associate Member
Department of Medical Oncology
Clinical Research Division, FHCRC
University of Washington
Seattle, Washington

Abdul Mikati, MD
Neurology resident, Dept. of Neurology
University of Massachusetts Medical School
55 Lake Ave North
Worcester, Massachusetts

Ann L. Mitchell, MD
Clinical Associate Professor University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, Massachusetts

Lawrence C. Mohr, Jr, MD, ScD, FACP, FCCP
Professor of Medicine, Biometry and Epidemiology
Director, Environmental Biosciences Program
Medical University of South Carolina
Charleston, South Carolina

Jahan Montague, MD
Clinical Associate Professor of Medicine
Director, Nephrology Fellowship
Department of Medicine
Division of Renal Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

Bruce Montgomery, MD
Professor
Department of Medicine
University of Washington and Seattle Cancer Alliance
Seattle, Washington

Majaz Moonis, MD, MRCP, DM, FRCP (I), FAAN, FAHA, FAASM
Professor of Neurology
Director of the Stroke Services
UMass Memorial Medical Center
Worcester, Massachusetts

Andrew H. Moraco, MD, MS
Fellow
Division of Pulmonary, Allergy and Critical Care
Department of Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

John P. Mordes, MD
Professor of Medicine/Endocrinology
Department of Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

David A. Morrow, MD, MPH
Professor of Medicine
Harvard Medical School
Directory, Levine Cardiac Intensive Care Unit
Division of Cardiovascular
Brigham and Women’s Hospital
Boston, Massachusetts

Babak Movahedi, MD, PhD
Assistant Professor of Surgery
Department of Surgery
Division of Organ Transplantation
UMass Memorial Medical Center
Worcester, Massachusetts

James B. Mowry, PharmD, DABAT, FAACT
Director, Indiana Poison Center
Emergency Medicine and Trauma Center
Indiana University Health Methodist Hospital
Indianapolis, Illinois

Karol Mudy, MD
Cardiothoracic Clinics
Hennepin County Medical Center
Minneapolis, Minnesota
Susanne Muehlschlegel, MD, MPH, FNCS, FCCM
Associate Professor of Neurocritical Care
Department of Neurology, Anesthesia, Critical Care and Surgery
University of Massachusetts Medical School
Worcester, Massachusetts

Diana Wells Mulherin, PharmD, BCPS, BCNSP
Clinical Pharmacy Specialist, Nutrition Support
Department of Pharmacy Clinical Programs and Center for Human Nutrition
Vanderbilt University Medical Center
Nashville, Tennessee

Saori A. Murakami, MD
Attending Psychiatrist
Assistant Medical Director, McLean Franciscan Child and Adolescent Inpatient Program
Child and Adolescent Psychiatry
McLean Hospital
Brighton, Massachusetts

John G. Myers, MD
Professor and Chief
Division of Trauma and Emergency Surgery
University of Texas San Antonio
San Antonio, Texas

It is with great pleasure that we present the eighth edition of *Irwin and Rippe’s Intensive Care Medicine*. As with previous editions, the editorial challenge that we faced with this edition was to continue to ensure that the book remained at the cutting edge, evolving as the field has evolved. It also needed to continue to meet the varied and rigorous demands placed on it by the diverse group of specialty physicians and nonphysicians practicing in the adult intensive care environment without losing strengths that have made previous editions very useful and popular. We believe that the eighth edition of *Irwin and Rippe’s Intensive Care Medicine* has met these challenges.

Over the past 32 years since the publication of the first edition of our book in 1985, dramatic changes have occurred in virtually every area of critical care, and these are reflected in the evolution of our book. Although our book initially focused primarily on medical intensive care medicine, it now provides an interprofessional emphasis on anesthesia, surgery, trauma, neuro and cardiovascular, as well as medical intensive care, with strong collaboration across all these disciplines. This reflects the reality that intensive care medicine has inevitably become more interprofessional and collaborative.

The eighth edition is approximately the same length as the previous edition. To update the text without expanding it, every section editor and author rose to the challenge and carefully balanced each chapter, emphasizing new evidence-based as well as state-of-the-art information and discarding outdated material. We take great pride in the quality of the section editors and chapter authors who have contributed to our eighth edition. All chapters in every section have been updated with recent references and other materials that reflect current information, techniques, and principles. New chapters have been added to reflect emerging areas of interest. An entirely new section has been added on “Palliative Care and Ethical Issues in the Critical Care Unit” that was ably edited by Jennifer E. Reidy.

Since publication of our last edition, point-of-care ultrasonography has become an important and arguably indispensable part of the bedside intensivist’s tool kit. As such, its use is prominently featured in this edition. To reflect the rising importance of this diagnostic and therapeutic tool to the practice of modern intensive care medicine, a total of five hours video materials have been embedded into 23 chapters to aid and educate intensivists on the use of this tool. Each video has been personally selected, edited, and narrated by one of our senior editors, Paul H. Mayo, who is internationally known for his knowledge and
Evidence-based medicine continues to play an ever-more prominent role in all branches of medicine including critical care. With this in mind, we have asked every chapter author, as in previous editions, to make recommendations that specifically reflect recent trials with a particular emphasis on prospective, randomized controlled trials. Authors have summarized such evidence when the data have allowed, with helpful tables.

In intensive care medicine, important changes and advances have occurred since the publication of the seventh edition. These include managing our ICUs according to the following guiding principles: (1) making our ICUs safer for our patients; (2) decreasing variability by following clinical practice guidelines based on the best available evidence to ensure better outcomes for our patients; and (3) doing more with less by choosing wisely to decrease the cost of caring for our patients. Although these principles have always been espoused, it has become clear that we must more consistently follow them. The appropriate uses of not only the electronic medical records, computer physician order entry, and clinical decision support tools, but also tele-ICU can help us operationalize these principles. All of these issues are covered in the section entitled “ICU Design, Organization, Operation, and Outcome Measures” edited by Neil A. Halpern.

With respect to managing cardiovascular problems and providing coronary care, it has been interesting to see how cardiovascular intensive care has dramatically changed since the publication of our first few editions as the advances in cardiology and cardiac surgery have become implemented. With respect to these problems, co-section editors Akshay S. Desai, David A. Morrow, and Patrick T. O’Gara have completely revamped their section to reflect the current state of their discipline.

Equally important advances have occurred in surgical critical care, shock, and trauma, including new therapies and techniques in a variety of conditions treated in this environment. These sections remain strengths of this book. We welcome new section editors, Mitchell Cahan for “Surgical Problems in the Intensive Care Unit” and Timothy A. Emhoff for “Shock, Trauma, and Sepsis Management.” Both have done masterful jobs updating these sections.

Although our book has been updated and broadened to include new understandings, information, and techniques, our goal has been to maintain the practical, clinically oriented approach that readers have come to expect from previous editions. Our editorial focus remains on clinically relevant studies and information that readers have found very useful in the previous seven editions.

As in the past, our book opens with a detailed section on commonly performed procedures, techniques, and ultrasound in the intensive care
unit, followed by a section covering minimally invasive monitoring. All chapters in these sections have been updated with new figures and descriptions of techniques that have been added to reflect changes since the seventh edition of the book. We are indebted to section editors Stephen O. Heard and Todd W. Sarge, who have done a superb job on these sections.

The Pharmacology, Overdoses, and Poisoning section, consisting of 30 chapters, remains a great strength of this book and essentially represents a textbook on the topics embedded into our larger book. For their tireless efforts on this outstanding and comprehensive section, we thank Luke Yip, Kennon Heard, and Steven B. Bird.

Our team of section editors continues to do a wonderful job coordinating large bodies of information that comprise the core of modern intensive care. Many of our section editors have been with us for one or more editions. Robert W. Finberg (Infectious Disease), Neil Aronin and David M. Harlan (Endocrinology), Stephanie M. Levine (Transplantation), Dominic J. Nompleggi (Gastroenterology and Metabolism/Nutrition), J. Mark Madison (Pulmonary), John Querques (Psychiatry), Nancy Y. N. Liu (Rheumatology), Pang-Yen Fan (Renal), Patrick F. Fogarty (Hematology and Oncology), Lawrence C. Mohr Jr. (Critical Care Consequences of Weapons [or Agents] of Mass Destruction), David A. Drachman and David Paydarfar (Neurology), and Joseph J. Frassica (Appendix, Calculations Commonly used in Critical Care) all fall into this category and have again made outstanding contributions.

As with previous editions, our emphasis remains on clinical management. Discussions of basic pathophysiology are also included and guided and supplemented by extensive references to help clinicians and researchers who wish to pursue more in-depth knowledge of these important areas. When therapies reflect institutional or individual bias or are considered controversial, we have attempted to indicate this.

We hope and believe that the outstanding efforts of many people over the past 5 years have continued to result in an evidence-based and state-of-the-art and comprehensive book that will elucidate the important principles in intensive care and will continue to guide and support the best efforts of practitioners in this challenging environment in their ongoing efforts to diagnose and treat complicated diseases and relieve human suffering.

Richard S. Irwin, MD, Master FCCP
Craig M. Lilly, MD, FCCP
Paul H. Mayo, MD, FCCP
James M. Rippe, MD
Numerous outstanding individuals have made significant contributions to all phases of writing and production of this book and deserve special recognition and thanks. First and foremost is our managing editor, Elizabeth Grady. Beth literally lives and breathes this book as it works its way through the production cycle every 4 to 5 years. She is the guiding and organizing force behind this book. It would simply not be possible without Beth’s incredible organizational skills, good humor, and enormous energy. She has guided this book through eight editions—this book is as much hers as it is ours.

The major innovation of this edition is the focus on point-of-care ultrasonography. Assisting Paul H. Mayo with the task of developing the high-quality ultrasound videos was Yonathan Greenstein, while assisting in preparation of the utility of ultrasonography sections were Gisela Banauch, Ariel Shiloh, and Lewis Eisen. For their outstanding work, we owe them a large debt of gratitude.

Our administrative assistants, office assistants, and clinical coordinators, Sherry Jakubiak and Cynthia French, Linda Doherty, Debra Adamonis, and Carol Moreau have helped us continue to coordinate and manage our complex professional and personal lives and create room for the substantial amount of time required to write and edit. Our section editors have devoted enormous skill, time, and resources to every editions of this book. We have very much appreciated their deep commitment to this book and to advancing the field of intensive care medicine.

Our editors at Lippincott Williams & Wilkins including Brian Brown, Executive Editor, have been a source of great help and encouragement. As with the last edition, Nicole Dernoski continues to be extremely helpful and accommodating in supervising and coordinating all phases of production in an outstanding way. Lauren Pecarich handled the day-to-day details necessary with a book of this size. Last, we are grateful to Samson Premkumar and his staff for the outstanding job they have done copyediting the manuscript for this edition.

It is with great sadness that we report that David A. Drachman passed away before the publication of the edition of this book. David was a good friend and wonderful colleague who had been the neurology section editor or co-editor on every one of the eight editions of *Intensive Care Medicine*. He will be greatly missed.

Our families support our efforts with unfailing encouragement and love. To them, and the many others who have helped in ways too numerous to count, we are deeply grateful.

Contents

Contributors List
Section Editors
Preface
Acknowledgments

Section 1  PROCEDURES, TECHNIQUES AND ULTRASONOGRAPHY

Chapter 1  Point-of-Care Critical Care Ultrasonography
Paul H. Mayo

Chapter 2  Anesthesia for Bedside Procedures
Mark Dershwitz

Chapter 3  Management of Pain in the Critically Ill
Mario De Pinto, Armagan Dagal, and Ramana K. Naidu

Chapter 4  Therapeutic Paralysis
Khaldoun Faris

Chapter 5  Cerebrospinal Fluid Aspiration
Firas Kaddouh, Susanne Muehlschlegel, and John P. Weaver

Chapter 6  Central Venous Catheters
Andrew H. Moraco and Scott E. Kopec

Chapter 7  Arterial Line Placement and Care
Carlos Martinez-Balzano and Scott E. Kopec
Chapter 8  Airway Management and Endotracheal Intubation  
J. Matthias Walz and Stephen O. Heard

Chapter 9  Tracheostomy  
Christine L. Bielick, Scott E. Kopec, and Timothy A. Emhoff

Chapter 10  Bronchoscopy  
Paulo J. Oliveira, Rahul N. Sood, and Richard S. Irwin

Chapter 11  Lung Ultrasonography  
Pierre Kory, Navitha Ramesh, and Paul H. Mayo

Chapter 12  Thoracentesis  
Mark M. Wilson and Richard S. Irwin

Chapter 13  Chest Tube Insertion and Care  
Ulises Torres and Joshua R. Scurlock

Chapter 14  Cardiopulmonary Resuscitation  
Bruce Greenberg and Abduljabbar Dheyab

Chapter 15  Cardioversion and Defibrillation  
Glenn Stokken, Mark S. Link, and Naomi F. Botkin

Chapter 16  Critical Care Echocardiography  
Brian Buchanan, Robert Arntfield, and Paul H. Mayo

Chapter 17  Pericardiocentesis  
Peeyush Grover and Craig S. Smith
Chapter 18  Temporary Cardiac Pacing
Brendan Merchant and Seth T. Dahlberg

Chapter 19  Pulmonary Artery Catheters
Harvey S. Reich

Chapter 20  Gastrointestinal Endoscopy
Samuel Y. Han, Randall Pellish, David R. Cave, and Wahid Y. Wassef

Chapter 21  Endoscopic Placement of Feeding Tubes
Lena M. Napolitano

Chapter 22  Gastroesophageal Balloon Tamponade for Acute Variceal Hemorrhage
Marie T. Pavini and Juan Carlos Puyana

Chapter 23  Paracentesis and Diagnostic Peritoneal Lavage
Lena M. Napolitano

Chapter 24  Interventional Radiology: Percutaneous Drainage Techniques
John-Paul B. Velasco, Brian T. Callahan, and Robert Sheiman

Chapter 25  Percutaneous Suprapubic Cystostomy
Philip J. Ayvazian

Chapter 26  Aspiration of the Knee and Synovial Fluid Analysis
Padmanaidu Karnam, Bonnie J. Bidinger, and Deborah M. DeMarco

Section 2  MINIMALLY INVASIVE MONITORING
Chapter 27  Routine Monitoring of Critically Ill Patients
Krysta S. Wolfe and Michael D. Howell

Chapter 28  Minimally Invasive Hemodynamic Monitoring
Brian S. Furukawa, Ednan K. Bajwa, Atul Malhotra, and Andrew J. Goodwin

Chapter 29  Echocardiography as a Monitor in the ICU
Achikam Oren-Grinberg, Todd W. Sarge, and Adam B. Lerner

Chapter 30  Respiratory Monitoring during Mechanical Ventilation
Melanie R. Loberman, Ray H. Ritz, and Todd W. Sarge

Chapter 31  Neurologic Multimodal Monitoring
Raphael A. Carandang and Wiley R. Hall

Chapter 32  Telemedicine and Critical Care Delivery
Lloyd C. Meeks, Shahzad Shaefi, and Craig M. Lilly

Section 3  PALLIATIVE CARE AND ETHICAL ISSUES IN THE CRITICAL CARE UNIT

Chapter 33  Integrating Palliative Care in the Intensive Care Unit
Nandita R. Nadig, Dana Lustbader, and Dee W. Ford

Chapter 34  Effective Communication and Ethical Decision-Making in the ICU
Daniel E. Ray, Jennifer E. Allen, and Karen M. Knops

**Chapter 35** Managing Symptoms in Critically Ill Patients
Richard Castriotta, Jennifer E. Reidy, Javier Barreda Garcia, Garbo Mak, and Brandy McKelvy

**Chapter 36** Being with Suffering: Addressing Existential and Spiritual Distress
Margaret Isaac, Suzana K. E. Makowski, and Christina Fitch

**Section 4** SHOCK AND TRAUMA AND SEPSIS MANAGEMENT

**Chapter 37** Resuscitation from Shock Following Hemorrhage
Jacob A. Quick, Donald H. Jenkins, John B. Holcomb, and Stephen L. Barnes

**Chapter 38** Trauma Systems
Daniel Hetherman and Timothy A. Emhoff

**Chapter 39** The Management of Sepsis
Paul E. Marik

**Chapter 40** Multiple Organ Dysfunction Syndrome
Timothy A. Pritts and Andrew C. Bernard

**Chapter 41** Traumatic Brain Injury
Wiley R. Hall and Raphael A. Carandang

**Chapter 42** Spinal Cord Trauma
Hanbing Zhou and Christian P. DiPaola
Chapter 43  Thoracic and Cardiac Trauma
Bruce J. Simon, Scott B. Johnson, and John G. Myers

Chapter 44  Critical Care of the Patient with Abdominal Trauma
Jon D. Dorfman

Chapter 45  Orthopedic Injury
Gregory J. Della Rocca, Sean E. Nork, Vivek Venugopal, and John J. Wixted

Chapter 46  Burn Management
Sean Figy and Joyce K. McIntyre

Section 5  SURGICAL PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 47  Surgeon and Intensivist Collaboration in the Care of the ICU Patient
Gustavo Guillermo Angaramo and Craig M. Lilly

Chapter 48  Surgical Infections in the Intensive Care Unit
Ann-Kristin U. Friedrich and Mitchell Cahan

Chapter 49  Care of the Patient with Necrotizing Fasciitis
Brandon Colvin, Benkole Samuel, and Hongyi Cui

Chapter 50  The ICU Management of Patients Undergoing Major Surgery for Gastrointestinal Cancers
Kate H. Dinh and Jennifer LaFemina

Chapter 51 The ICU Approach to the Acute Abdomen
James E. Carroll, Jr

Chapter 52 Abdominal Compartment Syndrome
Jon D. Dorfman

Chapter 53 Management of the Obstetrical Patient in the Intensive Care Setting
Anne Garrison

Chapter 54 Acute Limb Ischemia in the ICU Population
Dejah R. Judelson, Bing Shue, and William P. Robinson, III

Chapter 55 Palliative Surgery in the Intensive Care Unit
Laura A. Lambert

Section 6 TRANSPLANTATION

Chapter 56 Management of the Organ Donor
Christoph Troppmann

Chapter 57 Critical Care Problems in Kidney Recipients
Abbas A. Rana and Rainer W. G. Gruessner

Chapter 58 Critical Care of Liver Transplant Recipients and Live Liver Donors
Babak Movahedi, Paulo Martins, Sonia Nagy Chimienti, and Adel Bozorgzadeh
Chapter 59  Critical Care of the Lung Transplant Recipient
Luis F. Angel and Stephanie M. Levine

Chapter 60  Specific Critical Care Problems in Heart and Heart–Lung Transplant Recipients
Andrew W. Shaffer, Karol Mudy, and Sara J. Shumway

Chapter 61  Care of the Pancreas Transplant Recipient
Colleen L. Jay, Gregory A. Abrahamian, and Angelina Edwards

Chapter 62  Critical Care of Intestinal Transplant Recipients
Robert M. Esterl, Jr, William D. Payne, Abhinav Humar, and Ruy J. Cruz, Jr

Chapter 63  Immunosuppression in Solid-Organ Transplantation
Martin N. Wijkstrom, Sundaram Hariharan, and Abhinav Humar

Chapter 64  Hematopoietic Cell Transplantation
Ann E. Woolfrey, Marco Mielcarek, and Paul A. Carpenter

Chapter 65  Management of Graft-versus-Host Disease, Infection, Malignancy, and Rejection in Transplant Recipients
Vaughn E. Whittaker, Abbas A. Rana, David L. Dunn, and Rainer W. G. Gruessner

Section 7  RHEUMATOLOGIC, IMMUNOLOGIC, AND
DERMATOLOGIC DISEASES IN THE INTENSIVE CARE UNIT

Chapter 66  Rheumatologic Diseases in the Intensive Care Unit
Nancy Y. N. Liu and Judith A. Stebulis

Chapter 67  Vasculitis in the Intensive Care Unit
Paul F. Dellaripa and Donough Howard

Chapter 68  Therapeutics for Immune-Mediated Rheumatic Diseases
Peggy Wu

Chapter 69  Anaphylaxis
Frederic F. Little and Helen M. Hollingsworth

Chapter 70  Dermatology in the Intensive Care Unit
Julia Baltz, Kristen Berrebi, Dori Goldberg, Mary E. Maloney, and Haley Snadecki

Section 8  INFECTIOUS DISEASE PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 71  Approach to Fever in the ICU Patient
Raul E. Davaro and Richard H. Glew

Chapter 72  Prevention and Control of Healthcare-Acquired Infections in the Intensive Care Unit
Sumanth Gandra and Richard T. Ellison, III

Chapter 73  Use of Antimicrobials in the Treatment of Infection in the Critically Ill Patient
Iva Zivna, Richard H. Glew, and Jennifer S.
Chapter 74  Life-Threatening Community-Acquired Infections: Toxic Shock Syndrome, Meningococcemia, Overwhelming Postsplenectomy Infection, Malaria, Rocky Mountain Spotted Fever, and Others
Misha Huang and Mary T. Bessesen

Chapter 75  Acute Infection in the Immunocompromised Host
Jennifer S. Daly and Robert W. Finberg

Chapter 76  Intensive Care of Patients with HIV Infection
Thomas C. Greenough, Sarah H. Cheeseman, and Mark J. Rosen

Chapter 77  Infectious Complications of Drug Abuse
Afroza Liton and William L. Marshall

Chapter 78  Infective Endocarditis and Infections of Intracardiac Prosthetic Devices
Sarah H. Cheeseman, Karen C. Carroll, and Sara E. Cosgrove

Chapter 79  Infections Associated with Vascular Catheters
Payal K. Patel, Suzanne F. Bradley, and Carol A. Kauffman

Chapter 80  Urinary Tract Infections
Steven M. Opal

Chapter 81  Central Nervous System Infections
Chapter 82  Tuberculosis
Michelle K. Haas and Robert W. Belknap

Chapter 83  Serious Epidemic Viral Pneumonias
Daniel H. Libraty

Chapter 84  Middle East Respiratory Syndrome (MERS) Coronavirus
Christopher M. Coleman and Matthew B. Frieman

Chapter 85  Critical Care of Patients Infected with Ebola Virus
Steven Hatch

Chapter 86  Botulism
David M. Bebinger and Richard T. Ellison, III

Chapter 87  Tetanus
Mary Dawn T. Co and Richard T. Ellison, III

Section 9  HEMATOLOGIC AND ONCOLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 88  Disorders of Hemostasis in Critically Ill Patients
Alice D. Ma

Chapter 89  Transfusion Therapy: Blood Components and Transfusion Complications
Terry Gernsheimer
Chapter 90  Anemia in the Critical Care Setting
Marc S. Zumberg, Marc J. Kahn, and Alice D. Ma

Chapter 91  Thrombocytopenia
Thomas G. Deloughery

Chapter 92  Venous Thromboembolism and Associated Prothrombotic Disorders in the Intensive Care Unit
Eric S. Christenson, Sheetal Karne, Ashkan Emadi, and Michael B. Streiff

Chapter 93  Antithrombotic Pharmacotherapy
Kevin E. Anger, Christopher D. Adams, Bonnie C. Greenwood, Jeremy R. Degrado, and John Fanikos

Chapter 94  Critical Care of Patients with Hematologic Malignancies
Matthew J. Wieduwilt and Lloyd E. Damon

Chapter 95  Oncologic Emergencies
Eunpi Cho, Bruce Montgomery, Colleen Timlin, John A. Thompson, and Damian J. Green

Chapter 96  Therapeutic Apheresis: Technical Considerations and Indications in Critical Care
Laura S. Connelly-Smith and Theresa A. Nester

Section 10  PHARMACOLOGY, OVERDOSES, AND POISONINGS
Chapter 97  General Considerations in the Evaluation and Treatment of Poisoning  
Ian M. Ball

Chapter 98  Acetaminophen Poisoning  
Steven B. Bird

Chapter 99  Alcohols and Glycol Poisoning  
Jennifer L. Englund, Marco L. A. Sivilotti, and Marsha D. Ford

PROCEDURES, TECHNIQUES AND ULTRASONOGRAPHY

STEPHEN O. HEARD
Point-of-Care Critical Care Ultrasonography

PAUL H. MAYO

Critical care ultrasonography encompasses any application of ultrasonography that can be productively employed by the intensivist at the bedside for the diagnosis and management of the patient. In recognition of the importance of ultrasonography to intensive care medicine, the editors of this edition decided to incorporate the subject into the textbook insofar as possible. Where it is relevant, the reader will find within each chapter a section titled “Utility of Ultrasonography” that is written in cooperation with the chapter authors by a separate writing group, all of whom have been course leaders or senior faculty at American College of Chest Physicians national critical care ultrasonography courses and all of whom use ultrasonography in their daily critical care practice. Each ultrasonography section will connect to a video library coordinated with the subject matter of chapter that can be called out for review while reading the text. By design, the ultrasonography sections of the textbook do not emphasize technical aspects of machine design or ultrasound physics. These are well summarized in standard ultrasonography textbooks. Rather, the emphasis is on procedure- or disease-specific clinical applications of ultrasonography that are immediately relevant to the frontline intensivist, and that are well within their capability. The goal is to review those aspects of ultrasonography that a “typical” bedside intensivist would use on a routine basis. Complex aspects of ultrasonography are not part of the discussion, because they require expert level radiology and cardiology level capability.

COMPETENCE

By definition, the intensivist in charge of the case personally performs all aspects of the ultrasonography examination: image acquisition, image
interpretation, and application of the results at point of care. This is very different from ultrasonography performed by the consultative service of radiology and cardiology, where the examination is delayed in its performance, and where the consultant is disassociated from the clinical reality of case. In using ultrasonography at point of care, the intensivist uses an imaging modality that is uniquely suited to the demands of intensive care medicine: immediately available, relatively inexpensive, flexible, and with multipurpose applications.

Competence in key parts of critical care ultrasonography are summarized in the ACCP/SRLF Statement on Competence in Critical Care Ultrasonography [1]. This document lists the basic elements of the field that need to be mastered by the intensivist, and may be regarded as a minimum standard. This textbook reviews many other applications that are not listed in this Statement.

Competence in critical care ultrasonography requires mastery of image acquisition, image interpretation, and the cognitive elements of the field. Training in image acquisition may be accomplished initially on normal human subjects, but also requires scanning of patients under the direct supervision of a competent instructor. Training in image acquisition requires access to an image set that includes a large number of abnormal findings. The cognitive base is mastered by study of relevant material in a blended form comprising written material, lectures, or Internet-based information. Requirements for training relevant to the elements of the Competence Statement are summarized in the Statement on Training in Critical Care Ultrasonography that represents a multinational consensus on this subject [2].

At present, there is no national level certification process for critical care ultrasonography either in North America or any country in Europe. Competence is defined by local standards, so the intensivist has an important responsibility to seek out adequate training that focuses on achieving the standards defined in the Competence Statement. Some applications reviewed in this textbook are not mentioned in the Competence Statement, but have clinical utility. Competence in these is only assured by specific institutional standards. Critical care ultrasonography, once adopted by the active clinician, lends itself to an element of invention, local training effort, and adoption of techniques that are not initially widely used. One purpose of this textbook is to disseminate information on critical care ultrasonography that is not defined in the Competence Statement.

**Machine Requirements**

High-quality portable ultrasonography machines are widely available. Their cost is not prohibitive when compared to alternatives, such as
computerized tomography (CT), and their operating costs are low. In addition, a team that uses ultrasonography as its primary imaging tool reduces utilization of other standard imaging methods \[3\]; this accrues cost savings, because more expensive imaging modalities are not used as often. Most recent generation machines have good image quality (with a few exceptions), so purchase decision should be predicated on other factors. Some key questions to consider include the following:

1. Is the machine durable? Can the machine be dropped, can the transducers be dropped, and is it impervious to fluid spills?

2. What is the service record of the company? Is the cost of the service contract included in the price of the machine, or is the machine a “loss leader” that requires an expensive service contract in addition? What is the turnaround time for service?

3. Is the machine easy to operate? What is the turn-on time? Is the control surface simple and easy to operate? Is there well-designed memory capability that uses a widely accepted video image format?

4. Is the machine truly portable? Can it be easily removed from the stand for situations that require a hand-carried device? What is the footprint of the stand?

5. Can the machine and probes be easily and safely cleaned with disinfecting fluids?

The intensive care unit (ICU) machine requires two probes. The linear vascular probe is high frequency, so that it has excellent resolution, but poor penetration. This makes it ideal for vascular access, examination of pleural morphology, and to characterize structures near the skin surface such as lymph nodes. The phased array cardiac transducer has less resolution, but better penetration, because it is designed for examination of deeper structures. Most machines allow the phased-array cardiac transducer to be configured for abdominal scanning. This results in cost savings, because the machine does not then need to be equipped with a curvilinear abdominal transducer which adds significantly to acquisition cost.

---

**Machine Controls and Scanning Technique**

Even with a simple-to-operate portable machine, a common failure point for the inexperienced scanner is poor gain, depth, frequency, and
orientation control. This is remedied by effective hands-on training. Scanning technique is an important element of image acquisition. Excepting certain types of vascular access, the machine and the scanner are always placed on the same side as the patient. This permits the examiner to operate the machine controls with one hand while holding the probe with the other. This requires that the clinician be ambidextrous in terms of holding the probe, given that the patient may be surrounded by a variety of life support devices. Probe hold requires that some part of the hand rests on the patient while holding the probe in order to provide a stable image.

**Scope of Practice**

In considering the scope of practice of critical care ultrasonography, it is important to emphasize that not every intensivist needs to be competent in all aspects of the field. The consultative attending intensivist may not need any training, because their practice needs are not such that it is required. Other clinicians may wish to focus on procedural guidance with ultrasonography. For the active frontline intensivist, the Competence Statement is a good guide for the scope of practice, with additional skills added according to interest and practice requirements. This will require a higher level of training.

Competence should be defined by the scope of practice, but in some situations, there is an added layer of complexity. The hospital credentialing committee must grant the privilege to perform critical care ultrasonography. If the clinician has achieved competence during fellowship training as defined by their program director, hospital credentialing committees routinely grant privileges. This may not be the case for attending level intensivists, where other physician specialists perceive economic or political threat to granting the privilege to a physician who is not a radiologist or cardiologist. In this case, the intensivist may be competent, and yet be blocked from performing within their scope of practice. One solution to this problem is to provide strong evidence of training, such that the credentialing committee cannot but grant privileges. This evidence would include a comprehensive log of all scanning activity, cognitive training, image review, and course attendance. The American College of Chest Physicians has designed a training program to provide competence and to fulfil requirements to obtain hospital privileges.

**Limitations of Critical Care Ultrasonography**

Competence in critical care ultrasonography requires an understanding of its limitations. These include the following:
1. Related to patient factors: Obesity, heavy musculature, and edema may degrade the ultrasonography image to a major extent. The presence of subcutaneous air may block transmission of ultrasound, so that deeper structures cannot be visualized. Skin dressing and devices may block transmission of ultrasound. The critically ill patient often cannot be positioned for optimal image acquisition. For example, most critically ill patients are supine, so that posterior structures may be difficult to image.

2. Related to environmental factors: High ambient light levels degrade image quality. The patient may be surrounded by equipment that blocks access for scanning.

3. Related to the physics of ultrasonography: The physics of ultrasound limit the resolution and penetration of ultrasound in body tissues, and artifacts are common that may mimic abnormalities. Ultrasound is blocked by air owing to intense reflection such that the presence of air precludes any visualization of underlying structures. Bones markedly attenuate transmission of ultrasound, so that underlying structures are shadowed. Structures in the lung that are completely surrounded by air are invisible, ribs block visualization of the heart or brain, whereas gas-filled intestine blocks visualization of abdominal structures.

4. Related to the operator: The intensivist who performs critical care ultrasonography is responsible for all the aspects of image acquisition, interpretation, and application of the results to the clinical problem at hand. There is no expert radiologist or cardiologist to perform these critical functions. A limitation of critical care ultrasonography relates to the need for the intensivist to be fully trained and therefore competent in those aspects that are relevant to their practice needs.

5. Related to paradigm shift: The standard paradigm for imaging in the ICU is that the radiology or cardiology service is responsible for all aspects of image acquisition and interpretation. The intensivist is a passive participant in this process. The full integration of critical care ultrasonography into the daily function of the ICU requires a paradigm shift where the intensivists rely on their own skill at image acquisition and interpretation, and believe that ultrasonography often replaces standard imaging methods such as chest radiography and CT scan. As summarized by Öks et al.:

“This approach to critical care ultrasonography requires several dedicated machines, a number of frontline intensivists who are skilled at critical care ultrasonography, the deployment of ultrasonography as a primary tool on work rounds, a team decision to rely on ultrasonography as a primary imaging tool as
much as possible, and the decision that confirmatory imaging is not required for ultrasonography examinations performed by the MICU team.” [3]
CONCLUSIONS

Critical care ultrasonography is an important aspect of intensive care medicine. Rather than having several stand-alone chapters summarizing various aspects of ultrasonography, the editors have embedded ultrasonography in a disease- or procedure-specific manner that is clinically relevant to the frontline intensivist. The accompanying video library serves to provide guidance for a wide variety of critical care ultrasonography applications.
REFERENCES

When a patient in an intensive care unit (ICU) requires a bedside procedure, it is usually the attending intensivist, as opposed to a consultant anesthesiologist, who directs the administration of the necessary hypnotic, analgesic, and/or paralytic drugs. Furthermore, unlike in the operating room, the ICU usually has no equipment for the administration of gaseous (e.g., nitrous oxide) or volatile (e.g., isoflurane) anesthetics. Anesthesia for bedside procedures in the ICU is thus accomplished via a technique involving total intravenous anesthesia (TIVA).

COMMON PAIN MANAGEMENT PROBLEMS IN ICU PATIENTS

Dosing of Agent

Selecting the proper dose of an analgesic to administer is problematic for several reasons, including difficulty in assessing the effectiveness of pain relief, pharmacokinetic (PK) differences between the critically ill and other patients, and normal physiologic changes associated with aging.

Assessing the Effectiveness of Pain Relief

Critically ill patients often are incapable of communicating their feelings because of delirium, obtundation, or endotracheal intubation. This makes psychological evaluation quite difficult, because surrogate markers of pain intensity (e.g., tachycardia, hypertension, and diaphoresis) are inherent in the host response to critical illness.
Pharmacokinetic Considerations

Most of the pressors and vasodilators administered in the ICU by continuous intravenous (IV) infusion have relatively straightforward PK behavior: They are water-soluble molecules that are minimally bound to plasma proteins. In contrast, the hypnotics and opioids used in TIVA have high lipid solubility, and most are extensively bound to plasma proteins, causing their PK behavior to be far more complex. After a single or a few bolus injections, these medications are typically short acting because of rapid redistribution out of the brain. However, following infusions of long duration (i.e., hours or days), the processes of metabolism and elimination become more important and drug effects can have a longer duration.

The PK behavior of the lipid-soluble hypnotics and analgesics given by infusion may be described by their context-sensitive half-times (CSHTs). This concept may be defined as follows: When a drug is given as an IV bolus followed by an IV infusion designed to maintain a constant plasma drug concentration, the time required for the plasma concentration to fall by 50% after termination of the infusion is the CSHT [1]. Figure 2.1 depicts the CSHT curves for the medications most likely to be used for TIVA in ICU patients. PK behavior in critically ill patients is unlike that in normal subjects for several reasons. Because ICU patients frequently have renal and/or hepatic dysfunction, drug metabolism or excretion is often significantly impaired. Hypoalbuminemia, common in critical illness, decreases protein binding and increases free-drug concentration. Because free drug is the only moiety available to tissue receptors, decreased protein binding increases the pharmacologic effect for a given plasma concentration. It is therefore more important in the ICU patient that the doses of medications used for TIVA are individualized for a particular patient.
Physiologic Changes Associated with Aging

People 65 years of age and older comprise the fastest growing segment of the population and constitute the majority of patients in many ICUs. Aging leads to (1) a decrease in total body water and lean body mass; (2) an increase in body fat and, hence, an increase in the volume of distribution of lipid-soluble drugs; and (3) a decrease in drug clearance rates, because of reductions in liver mass, hepatic enzyme activity, liver blood flow, and renal excretory function. There is a progressive, age-dependent increase in pain relief and electroencephalographic suppression among elderly patients receiving the same dose of opioid as younger patients. There is also an increase in central nervous system (CNS) depression in elderly patients following administration of identical doses of benzodiazepines.

Selection of Agent

Procedures performed in ICUs today (Table 2.1) span a spectrum that extends from those associated with mild discomfort (e.g., esophagogastroscope) to those that are quite painful (e.g., orthopedic manipulations, wound debridement, tracheostomy). Depending on their technical difficulty, these procedures can last from minutes to hours. To provide a proper anesthetic, medications should be selected according to the nature of the procedure and titrated according to the patient’s response to surgical stimuli. In addition, specific disease states should be
considered in order to maximize safety and effectiveness.

</tbody>
</table>

<sup>a</sup>Procedures in which the level of discomfort may be significantly mitigated by the use of local anesthesia.

### Head Trauma

Head-injured patients require a technique that provides effective yet brief anesthesia, so that the capacity to assess neurologic status is not lost for extended periods of time. In addition, the technique must not adversely affect cerebral perfusion pressure. If the effects of the anesthetics dissipate too rapidly, episodes of agitation and increased intracranial pressure (ICP) may occur that jeopardize cerebral perfusion. In contrast,
if the medications last too long, there may be difficulty in making an adequate neurologic assessment following the procedure.

Coronary Artery Disease

Postoperative myocardial ischemia following cardiac and noncardiac surgery strongly predicts adverse outcome [2]. Accordingly, sufficient analgesia should be provided during and after invasive procedures to reduce plasma catecholamine and stress hormone levels.

Renal and/or Hepatic Failure

The association between sepsis and acute renal failure has been recognized for many years. The risk of an adverse drug reaction is at least three times higher in azotemic patients than in those with normal renal function. This risk is magnified by excessive unbound drug or drug metabolite(s) in the circulation and changes in the target tissue(s) induced by the uremic state.

Liver failure alters the volumes of distribution of many drugs by impairing synthesis of the two major plasma-binding proteins, albumin and $\alpha_1$-acid glycoprotein. In addition, reductions in hepatic blood flow and hepatic enzymatic activity decrease the clearance rates of many drugs.
CHARACTERISTICS OF SPECIFIC AGENTS USED FOR BEDSIDE PROCEDURES

Hypnotics

The characteristics of the hypnotics are listed in Table 2.2, and their recommended doses are listed in Table 2.3. When rapid awakening is desired, propofol or etomidate is the hypnotic agent of choice. Ketamine may be useful when a longer duration of anesthesia is needed. Midazolam is rarely used alone as a hypnotic; however, its profound anxiolytic and amnestic effects render it useful in combination with other agents. Dexmedetomidine does not reliably produce unconsciousness; however, its sedation is not accompanied by ventilatory depression and it potentiates opioid analgesia, thereby permitting lower opioid doses.

</table>
The “usual doses” are for patients without preexisting tolerance and significant cardiovascular disease. The required doses will be higher in patients with tolerance, and should be reduced in elderly patients and in patients with decreased cardiovascular function. In all cases, the medications should be titrated to specific end points as described in the text.

\[\text{\textsuperscript{a}}\text{Not recommended because of the possibility of prolonged adrenal suppression.}\]

### Propofol

#### Description

Propofol is a hypnotic agent associated with pleasant emergence and hangover characteristics. It is extremely popular because it is readily titratable and has more rapid onset and offset kinetics than midazolam. Thus, patients emerge from anesthesia more rapidly after propofol than after midazolam, a factor that may make propofol the preferred agent for sedation and hypnosis in general, and in particular for patients with altered level of consciousness.

The CSHT for propofol is about 10 minutes following a 1-hour infusion, and the CSHT increases about 5 minutes for each additional hour of infusion for the first several hours, as shown in Figure 2.1. Thus, the CSHT is about 20 minutes after a 3-hour infusion. The CSHT rises much more slowly for infusions longer than a day; a patient who is sedated (but not rendered unconscious) with propofol for 2 weeks will recover in approximately 3 hours [3]. This rapid recovery of neurologic status often makes propofol a desirable sedative in ICU patients, especially in those with head trauma, who may not tolerate mechanical ventilation without pharmacologic sedation.

Even though recovery following termination of a continuous infusion is faster with propofol than with midazolam, a comparative trial showed that the two drugs were roughly equivalent in effectiveness for overnight sedation of ICU patients [4]. For long-term sedation (e.g., more than 1 day), however, recovery is significantly faster in patients given propofol.

In spontaneously breathing patients sedated with propofol, respiratory rate appears to be a more predictable sign of adequate sedation than hemodynamic changes. The ventilatory response to rebreathing carbon dioxide during a maintenance propofol infusion is similar to that induced by other sedative drugs (i.e., propofol significantly decreases the slope of the carbon dioxide response curve). Nevertheless, spontaneously breathing patients anesthetized with propofol are able to maintain
normal end-tidal carbon dioxide values during most minor surgical procedures.

Bolus doses of propofol in the range of 1 to 2 mg per kg induce loss of consciousness within 30 seconds. Maintenance infusion rates of 100 to 200 μg/kg/min are adequate in younger subjects to maintain general anesthesia, whereas doses should be reduced by 20% to 50% in elderly individuals.

Adverse Effects

Cardiovascular. Propofol depresses ventricular systolic function and lowers afterload, but has no effect on diastolic function. Vasodilation results from calcium channel blockade. In patients undergoing coronary artery bypass surgery, propofol (2 mg per kg IV bolus) produced a 23% fall in mean arterial blood pressure, a 20% increase in heart rate, and a 26% decrease in stroke volume. In pigs, propofol caused a dose-related depression of sinus node and His-Purkinje system functions, but had no effect on atrioventricular node function or on the conduction properties of atrial and ventricular tissues. In patients with coronary artery disease, propofol administration may be associated with a reduction in coronary perfusion pressure and increased myocardial lactate production.

Neurologic. Propofol may improve neurologic outcome and reduce neuronal damage by depressing cerebral metabolism. Propofol decreases cerebral oxygen consumption, cerebral blood flow, and cerebral glucose utilization in humans and animals to the same degree as reported for thiopental and etomidate. Propofol frequently causes pain when injected into a peripheral vein. Injection pain is less likely if the injection site is located proximally on the arm or if the injection is made via a central venous catheter.

Metabolic. The emulsion used as the vehicle for propofol contains soybean oil and lecithin and supports bacterial growth; iatrogenic contamination leading to septic shock is possible. Currently available propofol preparations contain ethylenediamine tetraacetic acid (EDTA), metabisulfite, or benzyl alcohol as a bacteriostatic agent. Because EDTA chelates trace metals, particularly zinc, serum zinc levels should be measured daily during continuous propofol infusions. Hyperlipidemia may occur, particularly in infants and small children. Accordingly, triglyceride levels should be monitored daily in this population whenever propofol is administered continuously for more than 24 hours.

Etomidate

Description
Etomidate has onset and offset PK characteristics similar to propofol and an unrivaled cardiovascular profile, even in the setting of cardiomyopathy [5]. Not only does etomidate lack significant effects on myocardial contractility, but baseline sympathetic output and baroreflex regulation of sympathetic activity are well preserved. Etomidate depresses cerebral oxygen metabolism and blood flow in a dose-related manner without changing the intracranial volume–pressure relationship.

Etomidate is particularly useful (rather than thiopental or propofol) in certain patient subsets: Hypovolemic patients, multiple trauma victims with closed head injury, and those with low ejection fraction, severe aortic stenosis, left main coronary artery disease, or severe cerebral vascular disease. Etomidate may be relatively contraindicated in patients with established or evolving septic shock because of its inhibition of cortisol synthesis (see below).

**Adverse Effects**

**Metabolic.** Etomidate, when given by prolonged infusion, may increase mortality associated with low plasma cortisol levels [6]. Even single doses of etomidate can produce adrenal cortical suppression lasting 24 hours or more in normal patients undergoing elective surgery [7]. These effects are more pronounced as the dose is increased or if continuous infusions are used for sedation. Etomidate-induced adrenocortical suppression occurs because the drug blocks the 11β-hydroxylase that catalyzes the final step in the synthesis of cortisol. It is also noteworthy that etomidate causes the highest incidence of postoperative nausea and vomiting of any of the IV anesthetic agents.

In 2005, Jackson warned against the use of etomidate in patients with septic shock [8]. Since then, there have been several studies that have attempted to confirm or refute the safety of etomidate in critically ill patients, including those with sepsis. Unfortunately, some of these studies purportedly confirmed the danger of etomidate, whereas others support its continued use in patients with sepsis. Two recent meta-analyses of the available studies came to divergent conclusions [9,10]. Giving hydrocortisone to patients with septic shock may decrease overall mortality in patients who received etomidate for intubation as compared to other hypnotic agents [11].

**Ketamine**

**Description**

Ketamine induces a state of sedation, amnesia, and marked analgesia in which the patient experiences a strong feeling of dissociation from the environment. It is unique among the hypnotics in that it reliably induces
unconsciousness by the intramuscular route. Ketamine is rapidly metabolized by the liver to norketamine that is pharmacologically active. Ketamine is both slower in onset and offset as compared with propofol or etomidate following IV administration.

Many clinicians consider ketamine to be the analgesic of choice in patients with a history of bronchospasm. In the usual dosage, it decreases airway resistance, probably by blocking norepinephrine uptake that in turn stimulates beta-adrenergic receptors in the lungs. In contrast to many beta-agonist bronchodilators, ketamine is not arrhythmogenic when given to asthmatic patients receiving aminophylline.

Ketamine may be safer than other hypnotics or opioids in unintubated patients because it depresses airway reflexes and ventilatory drive to a lesser degree. It may be particularly useful for procedures near the airway, where physical access and ability to secure an airway is limited (e.g., gunshot wounds to the face). Because ketamine increases salivary and tracheobronchial secretions, an anticholinergic (e.g., 0.2 mg glycopyrrolate) should be given prior to its administration. In patients with borderline hypoxemia despite maximal therapy, ketamine may be the drug of choice, because ketamine does not inhibit hypoxic pulmonary vasoconstriction.

Another major feature that distinguishes ketamine from most other IV anesthetics is that it stimulates the cardiovascular system (i.e., raises heart rate and blood pressure). This action appears to result both from direct stimulation of the CNS with increased sympathetic nervous system outflow and from blockade of norepinephrine reuptake in adrenergic nerves.

Because pulmonary hypertension is a characteristic feature of acute respiratory distress syndrome, drugs that increase right ventricular afterload should be avoided. In infants with either normal or elevated pulmonary vascular resistance, ketamine does not affect pulmonary vascular resistance as long as constant ventilation is maintained, a finding also confirmed in adults.

Cerebral blood flow does not change when ketamine is injected into cerebral vessels. In mechanically ventilated pigs with artificially produced intracranial hypertension in which ICP is on the shoulder of the compliance curve, 0.5 to 2.0 mg per kg IV ketamine does not raise ICP; likewise, in mechanically ventilated preterm infants, 2 mg per kg IV ketamine does not increase anterior fontanelle pressure, an indirect monitor of ICP. Unlike propofol and etomidate however, ketamine does not lower cerebral metabolic rate. It is relatively contraindicated in
patients with an intracranial mass, with increased ICP, or who have suffered recent head trauma.

**Adverse Effects**

**Psychological.** Emergence phenomena following ketamine anesthesia have been described as floating sensations, vivid dreams (pleasant or unpleasant), hallucinations, and delirium. These effects are more common in patients older than 16 years, in females, after short operative procedures, after large doses (>2 mg per kg IV), and after rapid administration (>40 mg per minute). Pre- or concurrent treatment with benzodiazepines or propofol usually minimizes or prevents these phenomena [12].

**Cardiovascular.** Because ketamine increases myocardial oxygen consumption, there is risk of precipitating myocardial ischemia in patients with coronary artery disease if ketamine is used alone. On the other hand, combinations of ketamine plus diazepam, ketamine plus midazolam, or ketamine plus sufentanil are well tolerated for induction in patients undergoing coronary artery bypass surgery. Repeated bolus doses are often associated with tachycardia. This can be reduced by administering ketamine as a constant infusion. Ketamine produces myocardial depression in the isolated animal heart. Hypotension has been reported following ketamine administration in hemodynamically compromised patients with chronic catecholamine depletion.

**Neurologic.** Ketamine does not lower the minimal electroshock seizure threshold in mice. When administered with aminophylline, however, a clinically apparent reduction in seizure threshold is observed.

**Midazolam**

**Description**
Although capable of inducing unconsciousness in high doses, midazolam is more commonly used as a sedative. Along with its sedating effects, midazolam produces anxiolysis, amnesia, and relaxation of skeletal muscle.

Anterograde amnesia following midazolam (5 mg IV) peaks 2 to 5 minutes after IV injection and lasts 20 to 40 minutes. Because midazolam is highly (95%) protein bound (to albumin), the drug effect is likely to be exaggerated in ICU patients. Recovery from midazolam is prolonged in obese and elderly patients and following continuous infusion because it accumulates to a significant degree. In patients with renal failure, active conjugated metabolites of midazolam may
accumulate and delay recovery. Although flumazenil may be used to reverse excessive sedation or ventilatory depression from midazolam, its duration of action is only 15 to 20 minutes. In addition, flumazenil may precipitate acute anxiety reactions or seizures, particularly in patients receiving chronic benzodiazepine therapy.

Midazolam causes dose-dependent reductions in cerebral metabolic rate and cerebral blood flow, suggesting that it may be beneficial in patients with cerebral ischemia.

Because of its combined sedative, anxiolytic, and amnestic properties, midazolam is ideally suited both for brief, relatively painless procedures (e.g., endoscopy) and for prolonged sedation (e.g., during mechanical ventilation).

**Adverse Effects**

**Respiratory.** Midazolam (0.15 mg per kg IV) depresses the slope of the carbon dioxide response curve and increases the dead space–tidal volume ratio and arterial PCO$_2$. Ventilatory depression is even more marked and prolonged in patients with chronic obstructive pulmonary disease. Midazolam also blunts the ventilatory response to hypoxia.

**Cardiovascular.** Small (<10%) increases in heart rate and small decreases in systemic vascular resistance are frequently observed after administration of midazolam. It has no significant effects on coronary vascular resistance or autoregulation.

**Neurologic.** Because recovery of cognitive and psychomotor function may be delayed for up to 24 hours, midazolam as the sole hypnotic may not be appropriate in situations where rapid return of consciousness and psychomotor function are a high priority.

**Dexmedetomidine**

**Description**

Dexmedetomidine is the first $\alpha_2$-adrenoceptor agonist specifically marketed as a sedative. It is considerably more selective for $\alpha_2$-adrenoceptors than clonidine. The primary site of its action as a sedative is in the locus coeruleus, where its effect is to mimic physiologic sleep [13]. In rats, dexmedetomidine produces analgesia at the spinal cord level by activating descending inhibitory pathways originating in the midbrain, thereby reducing pain impulses that would otherwise ascend in the cord.

Dexmedetomidine produces intense sedation, although it cannot reliably produce amnesia, hypnosis, or general anesthesia [14]. It does not have anticonvulsant properties. As would be expected,
dexmedetomidine lowers blood pressure and heart rate, and dramatic decreases have occasionally occurred in patients without preexisting cardiovascular disease. Higher doses of dexmedetomidine can produce an initial increase in blood pressure that is believed to result from stimulation of \( \alpha_{2B} \)-adrenoceptors. Sympathetic stimulation is also responsible for the common side effect of dry mouth. Dexmedetomidine can markedly reduce the requirement for IV anesthetics and opioids. Sedative doses have very little effect on ventilation and do not appear to increase the ventilatory depressant effects of opioids [15].

Dexmedetomidine is approved for sedation of mechanically ventilated adult patients, but only for up to 24 hours, although longer trials have been published. The infusion typically is started near the end of an operative procedure before the patient is transported to the ICU or shortly after arrival. A bolus dose of 1 \( \mu \)g/kg is given over 10 minutes, followed by an infusion of 0.003 to 0.012 \( \mu \)g/kg/min. For infusions longer than an hour in duration, dexmedetomidine takes substantially longer to wear off than the other IV hypnotics as shown in Figure 2.1. No ventilatory depression is associated with dexmedetomidine, and patients should require less opioid for management of postoperative pain. The heart rate usually is slow, although symptomatic bradycardia occasionally occurs, and dexmedetomidine should not be given to patients with preexisting heart block. Postoperative hypertension usually is well controlled; however, some patients experience hypotension and require pressor infusion, especially if they have preexisting ventricular dysfunction. Two multicenter studies showed that ventilated patients who were sedated with dexmedetomidine required a shorter period of mechanical ventilation compared with midazolam (5.1 vs. 6.8 days, \( P = 0.03 \)), but not compared with propofol; the patients sedated with dexmedetomidine had more episodes of hypotension and bradycardia [16].

Dexmedetomidine is able to suppress postoperative shivering, probably via stimulation of \( \alpha_{2B} \) receptors in the hypothalamus. An intriguing possibility is that perioperative administration of an \( \alpha_{2} \)-adrenoceptor agonist decreases cardiovascular mortality. A meta-analysis concluded that such use decreases mortality and myocardial infarction after vascular surgery [17].

Opioids
Morphine

Description
Pain relief by morphine and its surrogates is relatively selective in that other sensory modalities (touch, vibration, vision, hearing) are not obtunded. Opioids blunt pain by (1) inhibiting pain processing by the dorsal horn of the spinal cord; (2) decreasing transmission of pain by activating descending inhibitory pathways in the brain stem; and (3) altering the emotional response to pain by actions on the limbic cortex.

Various types of opioid receptors (denoted by Greek letters) have been discovered in the CNS. The classical pharmacologic effects of morphine like analgesia and ventilatory depression are mediated by \( \mu \) receptors. Other \( \mu \) effects include sedation, euphoria, tolerance and physical dependence, decreased gastrointestinal motility, biliary spasm, and miosis. The \( \kappa \) receptor shares a number of effects with the \( \mu \) receptor, including analgesia, sedation, and ventilatory depression. The \( \delta \) receptor is responsible for mediating some of the analgesic effects of the endogenous opioid peptides, especially in the spinal cord. Few of the clinically used opioids have significant activity at \( \delta \) receptors at the usual analgesic doses.

Morphine is a substrate for P-glycoprotein, a protein responsible for the transport of many molecules out of cells. The combination of slow CNS penetration due to lower lipid solubility and rapid efflux accounts for the slow onset of morphine’s CNS effects. Peak analgesic effects may not occur for over an hour after IV injection; hence, the plasma profile of morphine does not parallel its clinical effects [18].

Morphine is unique among the opioids in causing significant histamine release after IV injection that occurs almost immediately. The beneficial effect of giving morphine to a patient with acute pulmonary edema is far more related to this hemodynamic effect rather than to its analgesic and sedating effects.

Adverse Effects

Gastrointestinal. Constipation, nausea, and/or vomiting are well-described side effects of morphine administration. Reduced gastric emptying and bowel motility (both small and large intestine), often leading to adynamic ileus, appear to be mediated both peripherally (by opioid receptors located in the gut) and centrally (by the vagus nerve). Fiber increasing agents, stool softeners, and mild cathartics are often prescribed for selected patients when a long duration of opioid analgesia requirement is expected.

Cardiovascular. Hypotension is not unusual following morphine administration, especially if it is given rapidly (i.e., 5 to 10 mg per
minute). In patients pretreated with both H₁- and H₂-antagonists, the hypotensive response following morphine administration is significantly attenuated, despite comparable increases in plasma histamine concentrations. These data strongly implicate histamine as the mediator of these changes.

**Respiratory.** Morphine administration is followed by a dose-dependent reduction in responsiveness of brain stem ventilatory centers to carbon dioxide. Key features of this phenomenon include a reduction in the slope of the ventilatory and occlusion pressure responses to carbon dioxide, a rightward shift of the minute ventilatory response to hypercarbia, and an increase in resting end-tidal carbon dioxide and the apneic threshold (i.e., the PCO₂ value below which spontaneous ventilation is not initiated without hypoxemia). The duration of these effects often exceeds the time course of analgesia. In addition to blunting the carbon dioxide response, morphine decreases hypoxic ventilatory drive. Morphine administration in renal failure patients has been associated with prolonged ventilatory depression secondary to persistence of its active metabolite, morphine-6-glucuronide.

The administration of small doses of IV naloxone (40 μg) to patients in order to reverse the ventilatory depressant effect of morphine may produce adverse effects. Anecdotal reports describe the precipitation of vomiting, delirium, arrhythmias, pulmonary edema, cardiac arrest, and sudden death subsequent to naloxone administration in otherwise healthy patients after surgery. Furthermore, the duration of action of naloxone is shorter than any of the opioids it may be used to antagonize (except remifentanil). Recurring ventilatory depression therefore remains a distinct possibility, and in the spontaneously breathing patient, it is a source of potential morbidity.

Reversal with a mixed opioid agonist–antagonist, such as nalbuphine or butorphanol, appears to be safer than with naloxone. Mixed opioid agonist–antagonist agents may either increase or decrease the opioid effect, depending on the dose administered, the particular agonist already present, and the amount of agonist remaining.

For bedside procedures in the ICU, many of these problems can be obviated by using a shorter-acting opioid.

**Neurologic.** Morphine has little effect on cerebral metabolic rate or cerebral blood flow when ventilation is controlled. Morphine may affect cerebral perfusion pressure adversely by lowering mean arterial pressure.

Фентанил и его сопряженные

**Description**
Fentanyl, sufentanil, and remifentanil enter and leave the CNS much more rapidly than morphine, thereby causing a much faster onset of effect after IV administration. The only significant difference among these agents is their PK behavior.

Fentanyl may be useful when given by intermittent bolus injection (50 to 100 μg), but when given by infusion, its duration becomes prolonged [19]. For TIVA in ICU patients in whom rapid emergence is desirable, sufentanil or remifentanil is the preferred choice for continuous infusion. When the procedure is expected to be followed by postoperative pain, sufentanil is preferred. Figure 2.1 shows that the CSHT of sufentanil is similar to that of propofol for infusions of up to 10 hours. When the procedure is expected to be followed by minimal postoperative pain (e.g., bronchoscopy), remifentanil is preferred. Its CSHT is about 4 minutes regardless of the duration of the infusion.

Remifentanil owes its extremely short duration to rapid metabolism by tissue esterases, primarily in skeletal muscle [20]. Its PK behavior is unchanged in the presence of severe hepatic [21] or renal [22] failure.

Sufentanil infusion for TIVA may be initiated with a 0.5 to 1.5 μg/kg bolus followed by an infusion at 0.01 to 0.03 μg/kg/min. If given with a propofol infusion, the two infusions may be stopped simultaneously as governed by the curves in Figure 2.1. Remifentanil infusion for TIVA may be initiated with a 0.5 to 1.5 μg/kg bolus followed by an infusion at 0.05 to 0.5 μg/kg/min. The remifentanil infusion should be continued until after the procedure is completed; if the patient is expected to have postoperative pain, another opioid should be given because the remifentanil effect will dissipate within a few minutes.

**Adverse Effects**

**Cardiovascular.** Although fentanyl, sufentanil, and remifentanil do not affect plasma histamine concentrations, bolus doses can be associated with hypotension, especially when infused rapidly (i.e., <1 minute). This action is related to medullary vasomotor center depression and vagal nucleus stimulation.

**Neurologic.** Fentanyl and sufentanil have been reported to increase ICP in ventilated patients following head trauma. Fentanyl and sufentanil may adversely affect cerebral perfusion pressure by lowering mean arterial pressure. All of the fentanyl derivatives may cause chest wall rigidity when a large bolus is given rapidly. This effect may be mitigated by neuromuscular blocking (NMB) agents as well as by coadministration
of a hypnotic agent.
NEUROMUSCULAR BLOCKING AGENTS

There are two pharmacologic classes of NMB agents (see Chapter 4): Depolarizing agents (e.g., succinylcholine) and nondepolarizing agents (e.g., rocuronium, vecuronium, and cisatracurium). Succinylcholine is an agonist at the nicotinic acetylcholine receptor of the neuromuscular junction. Administration of succinylcholine causes an initial intense stimulation of skeletal muscle, manifested as fasciculations, followed by paralysis due to continuing depolarization. Nondepolarizing agents are competitive antagonists of acetylcholine at the neuromuscular junction; they prevent acetylcholine, released in response to motor nerve impulses, from binding to its receptor and initiating muscle contraction. Distinctions among the nondepolarizing agents are made on the basis of PK differences as well as by their cardiovascular effects.

NMB agents are used to facilitate endotracheal intubation and improve surgical conditions by decreasing skeletal muscle tone. Prior to intubation, the administration of an NMB agent results in paralysis of the vocal cords, increasing the ease with which the endotracheal tube may be inserted and decreasing the risk of vocal cord trauma. During surgery, the decrease in skeletal muscle tone may aid in surgical exposure (as during abdominal surgery), decrease the insufflation pressure needed during laparoscopic procedures, and make joint manipulation easier during orthopedic surgery. NMB agents should not be used to prevent patient movement that is indicative of inadequate anesthesia. Dosing of NMB agents should be based on monitoring evoked twitch response; ablation of two to three twitches of the train-of-four is sufficient for the majority of surgical procedures and permits easy reversal.
PRACTICAL CONSIDERATIONS FOR TIVA

Electing to perform common procedures (e.g., tracheostomy, percutaneous gastrostomy) in the ICU instead of the operating room represents a potential cost saving and increases access to these procedures. Not only does this strategy eradicate costly operating room time and support resources, it eliminates misadventures that sometimes occur in hallways and on elevators. Cost analyses estimate an average overall cost reduction of 50% or more compared with traditional operative procedures [23]. TIVA represents the most cost-effective method of facilitating this.

In most patients, safe and effective TIVA may be achieved via the infusions of propofol plus sufentanil or remifentanil. Premedication with midazolam decreases the required propofol doses and decreases the likelihood of recall for intraoperative events. Bolus doses should not be used in hemodynamically unstable patients, and lower bolus doses should be used in elderly individuals. NMB agents are also given if needed.

The opioid infusion rate is titrated to minimize signs of inadequate analgesia (e.g., tachycardia, tachypnea, hypertension, sweating, mydriasis), although differentiation of pain from the sympathetic responses to critical illness is difficult. The propofol infusion rate is titrated to the endpoint of loss of consciousness; the depth of anesthesia monitors that are based on analysis of the EEG waveform (bispectral index, patient state index, or spectral entropy) facilitates locating this endpoint more objectively. Loss of consciousness should be achieved prior to the initiation of muscle paralysis. It is possible for patients to be completely aware of intraoperative events at times when there is no change in hemodynamics or any manifestation of increased sympathetic activity [24,25]. Hence, administering an opioid to blunt incisional pain without inducing loss of consciousness with a hypnotic is inappropriate.

The following additional points deserve consideration in this context:

1. In subhypnotic doses, propofol is less effective than midazolam in producing amnesia. In the absence of coadministration of a benzodiazepine, propofol must cause unconsciousness in order to reliably prevent recall. Prompt treatment of patient responses (movement, tachycardia, hypertension) is important.

2. Medications infused for TIVA should be given via a carrier IV fluid running continuously at a rate of at least 50 mL per hour. This method not only helps deliver medication into the circulation, but also serves
as another monitor of occlusion of the drug delivery system. Occlusion of the infusion line for more than a few minutes may lead to patient awareness.

3. In order to take advantage of the known CSHT values for the TIVA agents, communication with the surgeon during the procedure is important in order to anticipate the optimum time for stopping the infusions. Sufentanil and propofol infusions are stopped in advance of the end of the procedure, whereas remifentanil is infused until the procedure is completed.

4. To maintain reasonably constant propofol and sufentanil blood concentrations, the maintenance infusion rates should be decreased during the procedure because the plasma concentrations increase over time at constant infusion rates. An approximate guideline is to reduce the infusion rate by 10% every 30 minutes.

5. Strict aseptic technique is especially important during the handling of propofol.
REFERENCES

INTRODUCTION

In 2010, the International Association for the Study of Pain declared with the Declaration of Montreal that adequate pain management is a fundamental human right [1].

While goals of care in the intensive care unit (ICU) are mostly directed toward preventing mortality, it is equally, if not more important to consider the impact that morbidity may have on patients during the ICU phase of care; many decisions and interventions performed in the ICU can have a significant impact on the long-term well-being of patients.

In 2011, the Institute of Medicine estimated that 116 million Americans suffer from chronic pain, accounting for more health care costs than heart failure, diabetes, and cancer combined [2]. This report confirmed the significant impact pain has on our society.

We can look at the symptom pain as a dichotomy. On one hand, it is a signal of tissue damage and may offer protection from further insults. However, it can persist beyond the time of acute tissue damage, becoming a disease in its own right.

Pain may stem from acute medical or surgical illnesses as well as preexisting medical conditions. Mechanical ventilation, placement of indwelling tubes and catheters, procedures such as placement of chest tubes and intracranial pressure (ICP) monitors, turning and suctioning can all be causes of pain [3,4]. Exposure to high levels of pain can have negative psychological and physiological consequences, and its effective management is important in the maintenance of patient’s dignity [5–7].

Critically ill patients should have their pain systematically observed
and regularly assessed. All means of analgesic interventions should be evaluated in a coordinated, individualized, and goal-oriented interdisciplinary manner. Despite numerous improvement initiatives over the past two decades, pain is still a very common problem and often not treated appropriately for critically ill patients. It is estimated that as many as 70% of patients experience moderate-intensity procedure-related or postoperative pain during their stay in the ICU [8–11]. Pain is frequently treated inappropriately because of fears of depressing spontaneous ventilation, inducing opioid dependence, or precipitating cardiovascular instability. Moreover, many clinicians poorly understand the methods for assessing pain, the techniques for optimally treating it, and the benefits of its effective management. State-of-the-art pain management means not only decreasing pain intensity, but also reducing the side effects of anesthetics [12–14]. Studies also suggest that effective acute pain management may help reduce the development of chronic pain [15].

In 2005, the American Pain Society (APS) published guidelines for quality improvement in acute and cancer pain management [16]. In the guidelines, it is emphasized that it is important to recognize, identify, and treat pain promptly; involve patients and families in the pain management plan; reassess and adjust the pain management plan as needed; and monitor processes and outcomes of the pain management plan.

The primary goal of this structured approach to pain management is to prevent pain through the administration of analgesics at regular intervals and before performing potentially painful procedures. Implementation of the APS guidelines for 120 post–cardiac surgery patients over a 3-month period revealed that 95% had effective pain relief during every ICU staff shift for the first 6 days after surgery [17]. Analyses also revealed dramatically improved side-effect profile and reduced length of hospital stay. Implementation of a similar pain management protocol in a medical ICU resulted in a decrease in the number of days spent on the ventilator (from 10.3 to 8.9) and significant reductions of average hospital costs.

Pain management strategies for ICU patients should also incorporate the application of regional analgesia techniques (neuraxial and peripheral nerve blocks) whenever possible. While there are risks to the application and management of regional anesthesia and analgesia, these risks are
generally low enough with knowledgeable and experienced practitioners to warrant its use. Regional anesthesia, when used appropriately, helps to reduce the total amount of opioid analgesics necessary to achieve adequate pain control without the development of potentially dangerous side effects.
PHYSIOLOGIC EFFECTS OF ACUTE PAIN

Pain leads to the development of increased catabolism, immunosuppression, and prolonged sympathetic responses as a result of the combination of tissue injury and pain that can contribute to increased rates of morbidity and mortality. These effects can be subclassified as follows:

**Cardiovascular Effects**

- Increased heart rate
- Increased blood pressure
- Increased stroke volume
- Increased myocardial $O_2$ demands and reduced supply leading to myocardial ischemia

**Respiratory Effects**

- Stimulation of respiration causing initial hypocapnia and respiratory alkalosis
- Diaphragmatic splinting and hypoventilation, atelectasis, hypoxia, and hypercapnia
- Impaired respiratory secretion clearance leading to chest infections

**Endocrine Effects**

- Catabolic and anabolic changes
- Decrease in insulin production and action
- Reduction in testosterone levels
- Fluid retention

**Metabolic Effects**

- Raised blood glucose levels and immune dysfunction
Gastrointestinal Effects

Delayed gastric emptying
Nausea and anorexia
Reduced gastrointestinal (GI) motility and ileus

Coagulation

Procoagulant effects of immobility
Increased blood viscosity
Hypercoagulability and deep vein thrombosis (DVT)
EVALUATION OF PAIN AND SEDATION IN THE ICU PATIENT

Appropriate assessment of pain for the adult ICU patient can be challenging. Structured approaches to pain assessment are mandatory for optimal patient outcomes and to understand the severity of pain from a population health perspective. Pain assessment tools are useful to monitor for deterioration or improvements over time, and evaluate and titrate analgesic therapy appropriately \([7,18]\) (Fig. 3.1). There are several proposed methods available for pain assessment in the ICU. The chosen strategy should be adapted to the patient’s capacity to interact with the practitioner in order to provide assessment of static (rest) and dynamic (while moving the affected part or while taking deep breaths or coughing) pain.

**Five-Point Global Scale**

- None
- A little = 1
- Some = 2
- A lot = 3
- The worst = 4

**Verbal Quantitative Scale**

- 0 ........ 5 ....... 10
- None ........ Worst imaginable

**Visual Pain Analog Scale**

- No ........ Worst
- ...........................................
- Pain ........ Pain
- Place a mark on the line

**FIGURE 3.1** Several scales that can be useful for the evaluation of patient “self-reports” of pain before and after treatment.

Assessment of pain should include determining its cause(s), type, intensity, duration, site, and prior responses to therapy. Categorization of pain into somatic, visceral, neuropathic in nature and identification of specific sites and characteristics, such as focal bone pain as opposed to allodynia, or diffuse bowel distention, is important because it helps
determine the most effective type of intervention that improves the overall quality of pain care.

Subjective Pain Assessment

The **Visual Analog Scale** (VAS) is a 10-cm horizontal line, anchored by textual descriptors and/or pictures at each end. An end-point descriptor such as “no pain” (a score of 0) is marked at the left end and “worst pain imaginable” (a score of 10) is marked at the right end.

The **Numerical Rating Scale** (NRS) is a horizontal line with a scale from 0 to 10. Patients are asked to choose a number that relates to their pain intensity, where 0 represents no pain and 10 the worst imaginable pain. The NRS can be administered verbally or visually.

The **Faces Pain Scale** was first developed by Wong and Baker and is recommended for pediatric patients aged 3 and older. An explanation is given to the patient that each face is a person who feels happy because he or she has no pain or sad because he or she has some or a lot of pain. The patient is then asked to choose the face that best describes how they feel from six possible options.

NRSs have been reported to have the least variance and may be the preferred tool overall due to its rapid assessment. Mechanically ventilated and sedated patients will be unable to use the VAS ruler or other self-report pain assessment tools.

Objective Pain Assessment

When the patient is critically ill, sedated, and/or ventilated, pain severity can be estimated only by observing the behavioral and physiologic responses to pain:

The **Behavioral Pain Scale** (BPS) is the earliest and most widely tested pain assessment tool for sedated patients. There are three component domains:
- “facial expression”
- “upper limb movement”
- “compliance with ventilation”

Patients are scored from 1 to 4 on each section, giving a total score between 3 (no pain) and 12 (maximum pain) [19].

The **Critical Care Pain Observation Tool** (CPOT)
The CPOT has four domains:
“facial expression”
“body movement”
“muscle tension”
“compliance with ventilation”
Patients are scored in each section between 0 and 2, giving an overall score of 0 (no pain) to 8 (maximum pain) [11,20].

The Non-Verbal Pain Scale (NVPS)
The NVPS incorporates three behavioral domains and two physiologic domains. The behavioral domains are “face,” “activity (movement),” and “guarding.” The first physiologic domain considers vital signs and the second incorporates other indicators including skin color and temperature, perspiration, and pupillary changes. Again, specific descriptors are given to enable the assessors to rate a patient’s pain from 0 to 2 within each domain, giving a total pain score between 0 (no pain) and 10 (maximum pain) [21,22].

In general, none of these tools can be regarded as a gold standard and they require further evaluation and research to investigate the impact of their use on pain management in clinical practice. Nonetheless, they offer a consistent and systematic approach that might improve pain management in the ICU.

Analgesic trials can be another assessment tool if pain is suspected in ICU patients. They involve administration of a low dose of an analgesic followed by observation of the patient’s pain-related behavior [7,23].

The Pasero Opioid-Induced Sedation Scale (POSS) [24] is a tool used for assessing opioid-induced sedation. It ranges from S (sleepy and easy to arouse) through four levels of sedation based on how drowsy the patient is. The utility of this scale is that it can forewarn the development of opioid-induced respiratory depression if used routinely and correctly.

The Richmond Agitation Sedation Scale (RASS) in contrast to POSS is used to assess sedation and agitation. When opioids are administered and the goal of therapy is analgesia, the POSS should be employed. If the goal of therapy is sedation, the RASS should be used. Both tools can be used in parallel, but it is important to know what the goals of care are when using these tools.
FORMULATION OF A TREATMENT PLAN

It is important to understand the characteristics of the pathologic process responsible for pain in order to establish the most effective therapy.

Character and Site

The location of current pain and any preexisting pain location(s) should always be documented.

Pain can be categorized as follows:

- **Nociceptive pain** occurs in response to a noxious stimulus and continues only in the presence of a persistent stimulus. It is transmitted through nonmyelinated C-sensory fibers and small myelinated A-delta (δ) fibers, propagating the noxious stimuli via the dorsal root ganglions (DRG) and spino-thalamic pathways to the spinal cord, thalamus, periaqueductal gray, and other centers in the brain [25]. Nociceptive pain is often dull, aching, sharp, or tender and can be categorized into somatic and visceral pain.

  - **Somatic pain** is due to nociceptive signals arising from the musculoskeletal system and is generally well localized.

  - **Visceral pain** is due to a disease process or abnormal function of an internal organ or its covering (parietal pleura, pericardium, and peritoneum). It can be frequently associated with nausea, vomiting, sweating, and changes in heart rate and blood pressure and is often described as diffuse and not well localized.

- **Inflammatory pain** occurs after tissue injury and the subsequent inflammatory response. In order to help healing of the injured body part, the sensory nervous system undergoes a profound change; normally innocuous stimuli now produce pain, and responses to noxious stimuli are both exaggerated and prolonged [26] due to plasticity in nociceptors and central nociceptive pathways [27,28]. Ablation of a specific set of nociceptor neurons, such as the one expressing the tetrodotoxin-resistant sodium channel Nav1.8, eliminates inflammatory pain, but leaves neuropathic pain intact, indicating a fundamental difference in the neuronal pathways responsible for these pain states [29,30].

- **Neuropathic pain** can be sharp, shooting, burning, tingling, or electric in character. Patients with neuropathic pain may describe positive or negative neurologic phenomena. Positive phenomena include spontaneous pain (arising without stimulus) and evoked pains
(abnormal response to a stimulus). Negative phenomena include impaired sensation to touch or thermal stimuli. Neuropathic pain is initiated or caused by a primary lesion or dysfunction in the central or peripheral nervous system (CNS or PNS).

Central neuropathic pain most commonly results from spinal cord injury, stroke, or multiple sclerosis [31]. Peripheral neuropathic pain can be caused most commonly by [32]:

Trauma (e.g., complex regional pain syndrome [CRPS], persistent postsurgical pain)
Infection (e.g., postherpetic neuralgia, HIV-induced neuropathy)
Ischemia (e.g., diabetic neuropathy, peripheral vascular disease)
Metabolic (e.g., vitamin B$_{12}$ deficiency)
Cancer (e.g., invasion and compression of peripheral nerve structures)
Chemically induced (e.g., chemotherapy-induced neuropathy)
Radiation induced (e.g., medical radiation-induced neuropathy)

Damage to either the CNS or the PNS provokes maladaptive responses in nociceptive pathways that drive spontaneous pain and sensory amplification. This maladaptive plasticity leads to persistent changes and should be considered a disease state of the nervous system in its own right, independent of the etiologic factor(s) that trigger it. Studies suggest that peripheral and central sensitization mechanisms are also involved. In the PNS, they include altered gene expression and changes in ion channels that lead to ectopic activity. In the CNS, the expression of many genes is altered. In addition, synaptic facilitation and loss of inhibition at multiple levels of the neuraxis can produce central amplification. Neuronal cell death and aberrant synaptic connectivity provide the structural basis for persistently altered processing of both nociceptive and innocuous afferent inputs. Highly organized neuro-immunologic interactions as a result of neural damage play an important role in the development of persistent neuropathic pain. Genetically determined susceptibility is also likely to play a role in the development of neuropathic pain [30].

Hyperalgesia (an increased response to noxious stimuli), allodynia (the evocation of pain by non-noxious stimuli), hyperpathia (explosive pains
evoked in areas with an increased sensory threshold when the stimulus exceeds the threshold), dysesthesia (spontaneous or evoked unpleasant abnormal sensation), and paresthesia (spontaneous or evoked abnormal sensation) are typical elements of neuropathic pain.
MEDICAL MANAGEMENT OF PAIN FOR THE ICU PATIENT

Consequences of inadequate sedation and analgesia in the ICU may result in excessive pain and anxiety, agitation, self-removal of tubes and catheters, violence toward caregivers, myocardial ischemia, patient–ventilator dysynchrony, hypoxemia, and pain-related immunosuppression. In contrast, excessive and/or prolonged sedation can lead to skin breakdown, nerve compression, delirium, unnecessary testing for altered mental status, prolonged mechanical ventilation, and associated problems such as ventilator-associated pneumonia, and perhaps posttraumatic stress disorder. A balanced treatment approach using both nonpharmacologic and pharmacologic methods is necessary for optimal pain management of the ICU patient [33,34]. Improvement in quality of pain care may result in reductions of the time spent on mechanical ventilation and length of stay in the ICU.

Nonpharmacologic Treatments

Nonpharmacologic interventions are easy to provide, safe, and effective. They may include attention to proper positioning of patients to avoid pressure points, stabilization of fractures, and elimination of irritating physical stimulation (e.g., avoiding traction on the endotracheal tube). Several mechanisms have been proposed to explain how to inhibit or modulate the ascending transmission of a noxious stimulus from the periphery or, conversely, to stimulate descending inhibitory control from the brain [35]. They include the following:

- Gate control theory
- “Busy-line” effect
- Production of endogenous opioids at the periaqueductal gray, reticular activating system (RAS), and spinal gates
- Activation of monoaminergic neurons in the thalamus, hypothalamus, and brain stem
- Activation of second-order neurons in the dorsal horn, selective inhibition of abnormally hypersensitive neurons in the dorsal horn, and increased release of gamma (γ)-aminobutyric acid (GABA) from spinal neurons
Descending inhibition from supraspinal centers via the pretectal zone and posterior columns

*Stimulation-produced analgesia* is a term that describes noninvasive or minimally invasive techniques such as acupuncture, electroacupuncture, acupressure, transcutaneous electric nerve stimulation (TENS), spinal cord stimulation, peripheral nerve stimulation, DRG stimulation, deep-brain stimulation, and motor cortex stimulation. Evidence suggests that these modalities are useful as a sole or supplementary analgesic technique for both acute and chronic painful conditions [35]. Peripherally applied heat causes local vasodilation that promotes circulatory removal of biomediators of pain from the site of injury, whereas cold application decreases the release of pain-inducing chemicals [36].

Given that pain is an unpleasant sensory and emotional experience, it is always important to address the emotional component as well. Pain psychologists have primarily been used on an outpatient basis in pain clinics, but their importance on the inpatient side is significant, especially in the ICU where patients have already or are undergoing a potentially “traumatic” experience. The ICU experience is associated with major life changes such as financial hardship from the cost of health care, loss of function, or potential death. Having family and friends in proximity can be very helpful for a patient, although at times, it can be a detriment depending on the relationship and circumstances. Some institutions have therapy animals, which can provide a positive distraction for specific patients.

Modifications of the ICU environment, such as creating units with single rooms, decreasing noise, setting a schedule for activity, providing music and windows or appropriate lighting that better reflect a day–night orientation [37], may help patients achieve normal sleep patterns and also improve pain control. For the cognitively intact ICU patients, provision of sensory and procedural information may improve their ability to cope with the discomfort.

**Pharmacologic Treatments**

The pharmacologic characteristics of the ideal analgesic medication include easy titration, rapid onset and offset of action without accumulation, and no side effects.

**Cyclooxygenase Inhibitors—Nonsteroidal Anti-Inflammatory Drugs**
Cyclooxygenase (COX) is an enzyme located in all cells. It metabolizes arachidonic acid to generate prostaglandin $\text{H}_2$. A number of enzymes further modify this product to generate bioactive lipids (prostanoids) such as prostacyclin, thromboxane $\text{A}_2$, and prostaglandins $\text{D}_2$, $\text{E}_2$, $\text{F}_2$, and $\text{I}_2$. Isoforms COX-1 and COX-2 have been described. COX-1 is ubiquitous and constitutive. COX-2 is present in areas of inflammation and located in inflammatory cells. The COX-3 isoform was described in 2002 and was associated with a possible mechanism of action for acetaminophen but arguments exist as to why this is likely not so.

It is now recognized that COX-2 is expressed in normal endothelial cells in response to shear stress and its inhibition is associated with suppression of prostacyclin synthesis. Inhibition of COX-2 results in prothrombotic inclination on endothelial surfaces and an increase in sodium and water retention, leading to edema, as well as exacerbations of heart failure and hypertension. Loss of the protective effects of COX-2 upregulation in the setting of myocardial ischemia and infarction leads to a larger infarct size, greater thinning of the left ventricular wall in the infarct zone, and an increased tendency to myocardial rupture [38–40].

Blockade of the proinflammatory mediators by nonsteroidal anti-inflammatory drugs (NSAIDs) reduces the inflammatory response (and subsequent pain). Classically, their effect is anti-inflammatory, analgesic, and antipyretic because of the direct inhibition of prostaglandin production. Adding NSAIDs to intravenous (IV) opioid-based patient-controlled analgesia (PCA) reduces opioid consumption by 30% to 50% and results in a significant reduction in the incidence of nausea, vomiting, and sedation [41].

On the other hand, the nonspecific blockade of COX inhibits the physiologic role of COX-1 and results in clinically significant deterioration of renal function and risk of development of peptic ulcers and upper GI hemorrhage, bronchospasm, and platelet dysfunction. A meta-analysis published in 2002 has shown that the risk of GI hemorrhage is related to the patient and drug-related factors and is irrespective of the type of NSAID used. Patients who smoke, those with history of GI hemorrhage, and those taking anticoagulants are at increased risk [42]. Prophylaxis with a proton-pump inhibitor, histamine-2 antagonist, misoprostol, or sucralfate, reduces the risk of COX-1-related gastritis.

Current evidence indicates that selective COX-2 inhibitors have important adverse cardiovascular effects that include increased risk for
myocardial infarction, stroke, heart failure, and hypertension. The risk for these adverse effects is likely to be greatest in patients with a history of or at high risk for cardiovascular disease. These risks escalate with continued use after 30 days though it remains unclear if there is significant risk with short-term or “as needed” (PRN) use. In these patients, COX-2 inhibitors for pain relief should be used only if there are no alternatives and then only in the lowest dose and shortest duration necessary [43].

Opioid-sparing properties of NSAIDs have not been studied in critically ill patients, and so it is unclear if potential benefits outweigh potential risks such as GI bleeding or renal failure. Therefore, until more evidence for such agents becomes available, the clinician must carefully judge the risks and benefits on an individual basis.

**Acetaminophen—Paracetamol**

Acetaminophen is an analgesic and antipyretic. It may also have anti-inflammatory properties. The mechanism of action of acetaminophen remains unknown. Recent research indicates that acetaminophen inhibits prostaglandin synthesis in cells that have a low rate of synthesis and low levels of peroxide. When the levels of arachidonic acid are low, acetaminophen appears to be a selective COX-2 inhibitor. Acetaminophen has predominant effects on the CNS because the peroxide and arachidonic acid levels in the brain are lower than at peripheral sites of inflammation [44].

Acetaminophen is available in oral, rectal, and parenteral formulations. The parenteral formulation became available in the United States in 2010. It is an effective adjuvant to opioid analgesia, and a reduction in opioid requirement by 20% to 30% can be achieved when combined with a regular regimen of oral or rectal acetaminophen. One gram of acetaminophen significantly reduces postoperative morphine consumption over a 6-hour period. Doses greater than 1,000 mg have been reported to have a superior effect when compared with lower doses. IV acetaminophen has been shown to reduce PCA morphine requirements after spinal surgery [45] and hip arthroplasty. Its side-effect profile is comparable to placebo [46]; hypersensitivity reactions are rare. The major concerns with acetaminophen administration relate to the potential for hepatotoxicity, which is extremely rare following therapeutic dosing below 4 grams per day [47]. In patients with severe liver disease, the elimination half-life can be prolonged. A reduced dose of 1 gram two times a day with short duration of therapy is recommended. Prospective studies administering acetaminophen to patients consuming alcohol have found no increased evidence of liver injury [48]. Nonallergic hypotension has been reported in a cohort of ICU
patients treated with therapeutic doses of acetaminophen. Brain injury and sepsis are potential risks for this type of hypotensive reaction [49].

**Opioids**

For the critically ill patient, opioids remain the main pharmacologic method for the treatment of pain. Despite their extensive side-effect profile, there are no alternatives currently available with the same therapeutic range (Table 3.1).

CO, cardiac output; ICP, intracranial pressure; q, every.
Opiates refer to the nonpeptide synthetic morphine-like drugs, while the term opioid is more generic, encompassing all substances that produce morphine-like actions. Opioids can be loosely divided into four groups:

Naturally occurring, endogenously produced opioid peptides (e.g., dynorphin and Met-enkephalin)
Opium alkaloids, such as morphine or codeine, purified from the poppy (Papaver somniferum)
Semisynthetic opioids (modifications to the natural morphine structure), such as diacetylmorphine (heroin), hydromorphone, oxycodone, and oxymorphone
Synthetic derivatives with structure unrelated to morphine, which include the phenylpiperidine series (e.g., pethidine and fentanyl), methadone series (e.g., methadone and dextropropoxyphene), benzomorphan series (e.g., pentazocine), and semisynthetic thebaine derivatives (e.g., etorphine and buprenorphine)

Snyder et al. in 1973 reported on the presence of specific binding sites for opioids, providing the first evidence of the presence of distinct receptors for opioid medications. There are several types of opioid receptors. They differ in their potency, selective antagonism, and stereospecificity of opioid action. With a recent addition, the opioid receptor subtypes are listed as μ (MOR), κ (KOR), and δ (DOR), and nociceptin/orphanin FQ (N/OFQ) peptide receptor.

Opioids bind to the CNS and peripheral tissue receptors. μ₁-receptors mediate analgesia, whereas μ₂-receptor binding produces respiratory depression, nausea, vomiting, constipation, and euphoria. κ-receptor activation causes sedation, miosis, and spinal analgesia. In addition to analgesia, opioid receptors may provide mild-to-moderate anxiolysis. Opioids have no reliable amnestic effect on patients. Opioid administration is associated with a dose-dependent, centrally mediated respiratory depression. The respiratory rate is reduced, whereas the tidal volume is initially preserved. The ventilatory response to hypoxia is eradicated, and the CO₂ response curve is shifted to the right. Opioids facilitate patients’ compliance to the ventilator due to their cough-suppressant effects. Despite minimal cardiovascular effects in normovolemic patients, they may generate hypotension via decreased sympathetic tone and thus may decrease heart rate and systemic vascular resistance in critically ill patients. Additionally, some opiates can cause histaminergic vasodilation, which increases venous capacitance thereby decreasing venous return. Hypotension is more pronounced in
hypovolemic patients.

Endogenous $\mu$ opioid receptors play a role in homeostatic peristalsis. Exogenous $\mu$ opioids can lead to opioid-induced ileus and constipation, a common problem in the critically ill patient. Some opioids are used for this particular effect (e.g., loperamide [Imodium] an enteric $\mu$ receptor agonist marketed as an antidiarrheal). Other methods to manage constipation and ileus secondary to the use of opioids include stool softeners, promotility agents, osmotic agents, and $\mu$-receptor antagonists.

Morphine

Morphine has poor lipid solubility and thus has a relatively slow onset of action (5 to 10 minutes). The standard IV dose is 5 to 10 mg, and the approximate half-life is 3 hours. However, with repeated dosing or continuous infusions, half-life kinetics becomes unreliable. Morphine is conjugated by the liver to metabolites that include morphine-6-glucuronide, a potent metabolite with 20 times the activity of morphine. Both morphine and morphine-6-glucuronide are eliminated by the kidney; therefore, renal dysfunction results in a prolonged drug effect. Morphine-3-glucuronide is potentially neurotoxic and that can contribute to lowering the seizure threshold, the development of tremors, and, possibly, hyperalgesia. Morphine may also cause hypotension due to vasodilatation (secondary to the release of histamine).

Fentanyl

Fentanyl is highly lipid soluble with rapid onset of action (1 minute) and rapid redistribution into peripheral tissues, resulting in a short half-life (0.5 to 1.0 hour) after a single dose. The duration of action with small doses (50 to 100 $\mu$g) is short as a result of redistribution from the brain to other tissues. Larger or repeated doses, including those delivered via a continuous infusion, alter the context-sensitive half-time and result in drug accumulation and prolonged effects. The hepatic metabolism of fentanyl creates inactive metabolites that are renally excreted, making this drug a more attractive choice in patients with renal insufficiency. Fentanyl causes minor hemodynamic changes and does not affect inotropy.

Hydromorphone

Hydromorphone is a semisynthetic opioid that is five- to tenfold more
potent than morphine, but with a similar duration of action. It has minimal hemodynamic effects and causes minor to no histamine release \[50\]. While the metabolite hydromorphone-3-glucoronide has been found to be neurotoxic in animal studies, there have been very few clinical reports of hydromorphone-related neurotoxicity, and therefore practitioners prefer it to morphine. Studies suggest that patients who received IV hydromorphone have a greater decrease in pain than those given an equianalgesic dose of IV morphine \[51\].

**Methadone**

Methadone is a synthetic opioid agent with unique properties. It can be given enterally and parenterally. The bioavailability of the drug is highly variable and can be altered by the administration of antibiotics, antipsychotics, and antidepressants because it is metabolized through multiple CYP450 pathways (3A4, 2B6, 2D6, 2C9, 2C19, 2C8) whose function is also affected by those classes of drugs \[52\]. Methadone does not follow a linear conversion in that with increasing doses, there is an exponential increase in opioid requirements.

Methadone is an attractive choice for opioid analgesia due to its long half-life and low cost. It produces \textit{N}-methyl-\textit{D}-aspartate (NMDA) antagonism, which makes it ideal for neuropathic pain. Although methadone is not the drug of choice for an acutely ill patient whose hospital course is rapidly changing, it is a good alternative for the patient who has preexisting opioid tolerance or may need prolonged ventilatory wean. It may help facilitate the tapering of opioid infusions \[53\]. Metabolized in the liver, 40% of the drug is eliminated from kidney and free from active metabolites. It does not accumulate in renal failure.

**Oxycodone**

Oxycodone is effective for management of postoperative pain. It has a higher bioavailability and a slightly longer half-life than oral morphine. When transferring patients from oral morphine to oral oxycodone, the dose should be based on a 1.5:1 ratio (i.e., 1 mg oral morphine = 0.5 to 0.7 mg oral oxycodone). Individual patient variability and incomplete cross-tolerance require careful titration \[54\].

The use of controlled-release oxycodone (OxyContin) is indicated for the treatment of moderate-to-severe pain when continuous analgesia is required for prolonged periods. Due to concerns about misuse, the Food
and Drug Administration (FDA) has the ER/LA Risk Evaluation Mitigation Strategy program for the use of these drugs. Responding to concerns about misuse, the FDA approved an abuse-deterrent formulation of OxyContin in 2010 based on changes to the physical and chemical structure that makes it more difficult to inject or snort.

Remifentanil

Remifentanil (a derivative of fentanyl) is a powerful analgesic with an ultrashort duration of action. It is metabolized by nonspecific esterases to remifentanil acid, which has negligible activity in comparison. Its metabolism is independent from hepatorenal function. The context-sensitive half-time of remifentanil is consistently short (3.2 minutes), even after an infusion of long duration up to 72 hours [55].

In terms of safety, efficacy, and speed of onset and offset, remifentanil has been reported to have a better profile when compared with fentanyl [56]. When a morphine-based pain and sedation regimen was compared with another based on remifentanil, the mean duration of mechanical ventilation and extubation time were significantly shorter in the remifentanil group [57]. Breen et al. [58] compared a remifentanil-based analgesia–sedation regimen with another one based on midazolam and with the possible addition of fentanyl or morphine for analgesia, in a group of critically ill patients requiring prolonged mechanical ventilation for up to 10 days. The remifentanil-based sedation regimen was associated with significantly reduced duration of mechanical ventilation by more than 2 days.

Rozendaal et al. reported that in patients with anticipated short-term mechanical ventilation, a remifentanil–propofol analgesia–sedation regimen provides better control of sedation and agitation and reduces weaning time compared with conventional regimens. In addition, patients on a remifentanil–propofol–based regimen are almost twice as likely to be extubated and discharged from the ICU within the first 3 days of treatment than patients on conventional regimens [59]. In addition, remifentanil does not exert significantly prolonged clinical effects when administered to ICU patients with renal failure or chronic liver disease [55]. On the basis of these studies, it can be concluded that remifentanil is effective for providing both analgesia and sedation in critically ill patients, even those suffering from multiple organ failure. However, further data are needed to better guide clinicians on the use of this drug in ICU patients.
OPIOID SIDE EFFECTS

Opioid-related adverse effects occur commonly in the ICU [60]. Opioid-induced respiratory depression is generally dose related and is most deleterious for the spontaneously breathing ICU patient. The incidence of opioid-induced nausea and vomiting is low in the ICU. High-dose fentanyl may cause muscle rigidity. Opioid-induced hypotension occurs most commonly in patients who are hemodynamically unstable, volume depleted, or have a high sympathetic tone. The use of morphine is associated with histamine release; therefore, hypotension, urticaria, pruritus, flushing, and bronchospasm have been reported. Fentanyl can safely be used in patients with a suspected allergy to morphine. Excessive sedation from opioids is most often seen with the use of continuous infusions, particularly in patients with end-stage renal disease who are receiving fentanyl or morphine. Methadone may cause excessive sedation if the dose is not titrated downward after the first 5 days of therapy or if a human cytochrome P450 inhibitor is concomitantly administered. QTc-interval prolongation and the risk of development of torsades de pointes can occur with high doses of methadone because of its effects on the hERG channel, particularly if the chlorobutanol-containing IV formulation is used. Opioids may cause hallucinations, agitation, euphoria, sleep disturbances, and delirium [61]. Methadone may be the least likely drug to cause delirium because of its antagonistic activity at the NMDA receptor [62]. The effects of opioids on ICP in patients with traumatic brain injury remain unclear.

Ileus

Gastric retention and ileus are common in patients who are critically ill and receiving opioids. Prokinetic therapy and/or postpyloric access is often required in patients who are prescribed enteral nutrition. Prophylactic use of a stimulant laxative reduces the incidence of constipation. Methylnaltrexone, an opioid that does not cross an intact blood–brain barrier will only affect peripheral receptors and may have a role in treating opioid-induced constipation that fails to respond to laxative therapy [63]. Alvimopan has selectivity for peripheral μ receptors but is associated with an increased risk of myocardial infarction. Oral naloxone has been advocated for several years since it has very low bioavailability and can potentially antagonize enteric μ receptors without reversing analgesia. However, its use is not helpful when a patient already has impaired transit. Naloxegol, the most recent addition to the armamentarium, was approved in 2014. It adds polyethylene glycol to
naloxol, a compound close in chemical structure to naloxone.

**Addiction**

The possibility of developing addiction with patients receiving long-term opioids related to transient ICU stay–related pain is extremely low. Addiction is defined by the American Society of Addiction Medicine as a primary, chronic disease, of brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits leads to characteristic biologic, psychological, social, and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief by substance use and other behaviors. Addiction is characterized by inability to consistently abstain, impairment in behavioral control, craving, diminished recognition of significant problems with one’s behaviors and interpersonal relationships, and a dysfunctional emotional response. Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death [64].
OPIOIDS ADMINISTRATION METHODS

Opioid analgesics can be administered by either continuous infusion or titration to provide better pain control and less drug-related adverse effects. “As needed” protocols make it difficult to achieve adequate analgesic plasma concentrations, with resultant poor pain control.

When a continuous infusion is used, a sedation vacation protocol allows more effective analgesic titration with a lower total dose of opioid used. Daily awakening may also be associated with a shorter duration of ventilation and ICU stay. For patients in whom a long recovery and a prolonged ventilatory wean are anticipated, the use of a long-acting medication (e.g., methadone) to achieve adequate background pain control in combination with bolus doses of a short-acting opioid for management of breakthrough pain may be an appropriate option.

Conventional Routes of Administration (Oral, Intramuscular, and Subcutaneous)

Because of first-pass metabolism in the liver, larger doses of medications are required when oral preparations are used. Immediate-release oral opioids (e.g., morphine, oxycodone, hydromorphone) are usually preferred. Onset of analgesia is obtained in 45 to 60 minutes with these medications. Fixed-interval dosing (e.g., every 4 hour) is preferable to a “when required” regimen to ensure adequate relief of moderate-to-severe pain. The rectal route is rarely used in the ICU, even though drugs absorbed from the lower half of the rectum bypass the portal vein and first-pass metabolism in the liver. Suppository formulations containing morphine, oxycodone, hydromorphone, and oxymorphone are available.

Intramuscular injections of opioids are useful if there is a lack of personnel trained to administer IV injections or if venous access is difficult. The intramuscular injection of morphine takes 30 to 60 minutes to be effective. Absorption of intramuscular opioids is variable and depends on the injection site, especially in critically ill patients. Subcutaneous injection via an indwelling cannula in the subcutaneous tissue of the upper outer aspect of the arm or thigh is a useful alternative route of administration. The rate of absorption of morphine after subcutaneous injection is similar to that of an intramuscular injection; therefore, the guidelines for titration are the same (Table 24.1)
Advanced Methods of Administration

The IV route is the preferred route of administration. There is less variability in blood levels when the IV route is used, making it easier to titrate the drug to an effective analgesia concentration. IV infusions are a commonly used method. An opioid infusion at a fixed rate takes five half-lives of the drug to reach 98% of a steady-state concentration. Therefore, a front-loading dose is needed to achieve adequate pain relief more rapidly before starting the infusion. If breakthrough pain occurs, more IV bolus doses may be needed to reestablish pain relief before the infusion rate is increased.

IV PCA devices allow the patient to self-administer a predetermined dose of opioid within the limits of a lockout period. This results in less variability in the blood levels of the drug, thereby enabling titration of the drug to effect [65].

The epidural and intrathecal routes of administration provide a more rapid analgesia due to the application of the drug directly within the CNS. Patient-controlled epidural analgesia (PCEA) regimens allow better titration of the medication. In general, the analgesic efficacy of neuraxial opioids is greater than that achieved with parenteral opioid administration, resulting in superior pain relief despite the smaller doses used in the subarachnoid or epidural space (e.g., subarachnoid morphine 0.1 mg = epidural morphine 1 mg = IV morphine 10 mg). Opioid solutions with preservative-free formulations should be used for neuraxial administration to avoid potential neurotoxicity.

Highly lipid-soluble opioids (e.g., fentanyl, buprenorphine) have been formulated as a skin patch for transdermal delivery, especially in the management of severe pain in chronic and palliative care. Fentanyl patches are usually not a recommended modality for acute analgesia because of their 12- to 24-hour delay to peak effect and similar lag time to complete offset once the patch is removed. However, it is appropriate to continue its use in the ICU if the patient has a known history of using this formulation of the medication before admission.

Given its peculiar pharmacologic characteristics (high affinity for the \( \mu \) opioid receptor, antagonism at the \( \kappa \) opioid receptor, long half-life of approximately 24 hours), it is appropriate to discontinue the use of transdermal buprenorphine for patients who may require a long ICU stay. Because of the high affinity of buprenorphine for the \( \mu \) receptor, high doses of other opioids with high affinity for the receptor (hydromorphone, fentanyl) may be necessary to achieve adequate pain control in these patients, especially during the initial phases of care.
ADJUVANT MEDICATIONS

Ketamine

Ketamine is a dissociative anesthetic that can be used for sedation and/or anti-hyperalgesia. It possesses strong analgesic properties at higher doses. It acts both centrally and peripherally by inhibition of glutamate activation via noncompetitive antagonism at the phencyclidine receptor of the NMDA channel. Nitric oxide (NO) synthase inhibition also contributes to its effects.

Water- and lipid-soluble characteristics of ketamine hydrochloride enable the IV, intramuscular, subcutaneous, epidural, oral, rectal, and transnasal routes of administration. Ketamine has a rapid onset and short duration of action [66]. Following metabolism in the liver, norketamine is produced, which is significantly less potent (20% to 30%) when compared with ketamine.

In subanesthetic or low doses (0.1 to 0.5 mg per kg IV or as an infusion at doses of 1 to 5 μg/kg/min), ketamine demonstrates significant anti-hyperalgesic efficacy without significant adverse pharmacologic effects. There is evidence that ketamine as an adjunct to a pain management plan reduces opioid consumption. Low-dose ketamine may play an important role in postoperative pain management when used as an adjunct to opioids, local anesthetics, and other analgesic agents [67–69]. Administration of regular benzodiazepines should be considered to minimize the risk of developing psychomimetic side effects associated with its use.

Ketamine infusions have been used for critically ill ICU patients who are very difficult to sedate with opioid and benzodiazepines. Because of the potential risk for developing hallucinations and vivid dreams, increased ICP, and myocardial depression, ketamine is not recommended for routine sedation and analgesia of the critically ill patient, but it can be useful for more difficult situations and/or when short surgical procedures with intense pain, such as placement of chest tubes, dressing changes, and/or wound debridement in burn patients, are necessary.

α2-Adrenergic Agonists

α2-Adrenergic activation represents an intrinsic mechanism of pain control at the level of the CNS. α2-Adrenergic receptors exist in large numbers in the substantia gelatinosa of the dorsal horns of the spinal cord in humans. Agonists produce their pain control effect on those
receptors.

**Clonidine**

Clonidine produces analgesia after systemic, epidural, or intrathecal administration. It has a short duration of action after a single dose and may produce sedation, bradycardia, and hypotension. Clonidine improves opioid analgesia and potentiates the effect of local anesthetic [70,71]. Its use for the ICU patient must be carefully considered, especially in patients with hemodynamic and cardiovascular instability.

**Dexmedetomidine**

Dexmedetomidine is a centrally acting $\alpha_2$-agonist with sedative and analgesic properties. It has a much greater affinity for the $\alpha_2$-receptors than clonidine. The sedative properties are facilitated through the locus coeruleus in the CNS. Analgesic effects occur via activation of the $\alpha_2$-receptors and through potentiation of the action of opioids [72]. The drug causes no significant effect on the respiratory drive even when used with opioids. Dexmedetomidine has a biphasic effect on the cardiovascular system. The initial bolus injection is associated with vasoconstrictive effects, causing bradycardia and hypertension. Continuous infusion is associated with hypotension secondary to vasodilation caused by central sympatholysis. Studies conducted in postoperative ICU patients demonstrated successful short-term sedation and analgesic sparing effects [73]. There are a few studies examining long-term administration to critically ill, mechanically ventilated patients with encouraging results [74]. Suggested dosing recommendations would be a loading dose of 1 $\mu$g per kg over 10 minutes followed by an infusion at a rate of 0.2 to 0.7 $\mu$g/kg/h.

**Lidocaine**

Lidocaine has known analgesic, anti-hyperalgesic, and anti-inflammatory properties and some evidence to support the use of lidocaine infusions for pain management in selected group of patients has been reported. Little is known about the incidence of risks associated with this type of intervention. However, in a recent review on the use of lidocaine infusions, its use was deemed safe when utilized in surgical patients at the appropriate dosing and when the appropriate contraindications are
considered [75].

Lidocaine infusions are appropriate in patients undergoing major abdominal surgery, colorectal surgery in particular. Its use can reduce overall opioid requirements, ileus recovery time, and hospital length of stay [76,77]. However, one study comparing the use of IV lidocaine infusions with thoracic epidural analgesia (TEA) concluded that lidocaine does not reduce opioid consumption and pain scores when compared with TEA [78]. However, a lidocaine infusion may be considered for patients who may not be appropriate candidates for TEA (e.g., patient refusal, need for full-dose anticoagulation, presence of a localized or widespread infection).

The use of lidocaine infusions is contraindicated in patients with a known history of cardiac conditions such as atrio-ventricular conduction blockade and should be used with caution in patients with hepatic dysfunction. Serum levels should be obtained if one is concerned with systemic toxicity; the literature suggests that the threshold for lidocaine systemic toxicity is 5 μg per mL.

**Antiepileptic Drugs—Calcium-Channel Membrane Stabilizers**

Gabapentin and pregabalin (Gabapentinoids) are licensed for the management of neuropathic pain.

Despite its structural similarity to GABA, gabapentin does not bind to GABA receptors. It has a high affinity for α2/δ-subunits of voltage-dependent calcium channels, resulting in postsynaptic inhibition of the calcium influx thereby reducing the presynaptic excitatory neurotransmitter release [79]. It markedly decreases postoperative opioid consumption when given at the time of anesthetic induction [80]. Several randomized controlled trials (RCTs) using different pain models have shown a positive effect of the gabapentinoids on postoperative pain in humans. Single doses of gabapentin up to 1,200 mg have been shown to reduce pain scores and/or morphine consumption after abdominal and vaginal hysterectomy, lower limb arthroplasty, and laparoscopic cholecystectomy. Different meta-analyses have confirmed these effects, which can persist for up to 24 hours after surgery [81]. Common side effects of these medications include dizziness and drowsiness. Gabapentin has minimal drug interactions.

Pregabalin has the same mechanism of action of gabapentin. It has higher efficacy due to its linear pharmacokinetics. In addition, it appears to have a faster onset of action, due in part to its smaller volume of distribution.
Neuraxial anesthesia and peripheral nerve blockade have the potential to reduce or eliminate the physiologic stress response to surgery and trauma, decreasing the risk of surgical complications and reducing the development of chronic pain. By optimizing pain control with regional anesthesia techniques, patient satisfaction scores and outcomes improve.

When used alone or in combination with other treatment modalities, regional analgesia techniques are an invaluable tool to address pain-related problems in critically ill patients, but the indications for their use must be established correctly. ICU patients are at risk for numerous complications, and the use of an inappropriate regional analgesia technique can cause a deterioration of the patient’s clinical status, affecting potentially favorable outcomes.

The purpose of this section is to discuss risk and benefits of neuraxial and peripheral nerve blockade for the management of pain in the critically ill patient.

**General Considerations**

The use of ultrasound (US) technology in regional anesthesia allows an easier and more reliable identification of neural structures, the safe administration of lower doses of local anesthetic, and the insertion of nerve catheters even in the heavily sedated ICU patients. Ultrasound-guided (USG) techniques have reduced misplacement and failure rates in clinical practice. Effective identification of the needle allows for the reduction of the amount of administered drug volumes, which may be of importance in the critically ill, children, and patients who need more than one block, especially those who have undergone multisite surgery or sustained multiple injuries [82].

Regional analgesia techniques also effectively block sympathetic outflow. Many studies have shown that surgically related stress is reduced when regional anesthesia and analgesia techniques are used, neuraxial techniques in particular. The use of neuraxial analgesia has also been reported to decrease the rate of postoperative myocardial infarctions, shorten postoperative and posttraumatic ileus, improve the outcome, and shorten the length of ICU stay [83].

The use of such techniques may also reduce the incidence of chronic pain in patients undergoing surgical procedures, such as limb amputations and thoracotomies, two procedures in particular associated with the development of chronic persistent postsurgical pain [84].
Nerve Blocks for Thoracic and Abdominal Wall

Intercostal Nerve Blocks

Single and continuous intercostal nerve blocks are used to provide analgesia in patients with thoracic injuries and rib fractures and for the treatment of postoperative pain. Excellent pain relief and improvement in pulmonary mechanics have been reported [85]. Intercostal nerve blocks are associated with risk of pneumothorax and systemic local anesthetic toxicity. The patient’s coagulation status must be checked to prevent the risk of bleeding and hematoma formation subsequent to the laceration of an intercostal vessel. Continuous intercostal nerve blockade after thoracotomy using an extrapleural catheter consistently results in better pain relief and preservation of pulmonary function than the use of systemic opioids and appears to be at least as effective as the relief provided by the epidural approach. The ease of the extrapleural approach and the low incidence of complications suggest that this technique should be used more frequently. Other methods of intercostal nerve blockade appear to be less effective. The use of a multifaceted approach to postthoracotomy analgesia that includes intercostal nerve blockade has been shown to be beneficial in the immediate postoperative period, as well as reduce the incidence of chronic pain.

Major pulmonary resections, which have been managed with a mini-thoracotomy and intrapleural intercostal nerve blockade, have been associated with reduced postoperative pain and improved outcomes. However, a recently published study in thoracotomy patients did not find a measurable difference in pain relief between intercostal catheters and epidural analgesia [86].

Although not frequently used, intercostal nerve blockade can be extremely useful for the ICU patient, especially when used as a single injection for painful procedures (e.g., placement of chest tubes), or as an infusion when the patient’s hemodynamic conditions do not allow the use of TEA.

Paravertebral Block

Paravertebral nerve blocks (PVBs) provide analgesia for thoracic and upper abdominal pain. Paravertebral nerve blockade can be performed with a single injection or a continuous catheter technique [87]. Injection
of contrast material into a paravertebral catheter shows flow of the dye laterally into the intercostal space, as well as up and down the ipsilateral paravertebral space, leading to the spreading of local anesthetics over several dermatomal levels.

The advantages of PVBs are similar to those of the intercostal nerve block technique. Analgesia can be obtained without the development of potentially deleterious widespread cardiovascular effects because only unilateral sympathetic blockade is produced.

Because the site of injection is medial to the scapula, this block is easier to perform at high thoracic levels than the intercostal nerve blocks. In contrast to routine intercostal blocks, the posterior primary ramus of the intercostal nerve is also covered with the paravertebral approach, providing analgesia of the posterior spinal muscles and the costovertebral ligaments.

Failure rate after PVB in adults varies from 6.1% to 10.7% and compares favorably with other regional procedures. In a prospective study of 319 adult patients, the incidence of complications after thoracic or lumbar PVB was reported to be as follows: hypotension 5%, vascular puncture 3.8%, pleural puncture 0.9%, and pneumothorax 0.3% [88,89].

**Interpleural Analgesia**

Interpleural blockade is a technique by which an amount of local anesthetic is injected into the thoracic cage between the parietal and visceral pleura to produce ipsilateral somatic block of multiple thoracic dermatomes. Local anesthetic solutions can be administered as single or intermittent boluses, or as continuous infusions via an indwelling interpleural catheter. It has been shown to provide safe, high-quality analgesia after cholecystectomy, thoracotomy, renal surgery, breast surgery, and some invasive radiologic procedures of the renal and hepatobiliary system. It has also been used successfully in the treatment of pain from multiple rib fractures, herpes zoster, CRPS, thoracic and abdominal cancer, and pancreatitis [85].

There are several methods proposed for the detection of the entry of the needle into the pleural space, and all of them involve the detection of the “negative pressure” when the needle has entered into the intrapleural space [90]. If a posterior approach is not possible, an anterior approach can be used. The catheter may also be positioned in the interpleural space under direct vision during surgery.

The risk of pneumothorax is 2%. The risk of systemic local anesthetic toxicity is 1.3%. Pleural inflammation increases the risk of toxicity. It has been suggested that local anesthetic solution diffuses outward with the interpleural technique blocking multiple intercostal nerves, the sympathetic chain of the head, neck and upper extremity, the brachial
plexus, splanchnic nerves, the phrenic nerve, the celiac plexus, and ganglia. As the injected local anesthetic diffuses out through both layers of the pleura, direct local effects on the diaphragm, lung, pericardium, and peritoneum may also contribute to some of its analgesic activity [86].

**Transversus Abdominis Plane Block**

Incisional pain represents a considerable portion of postoperative pain following abdominal operations. The abdominal wall consists of three muscle layers: external oblique, internal oblique, transversus abdominis, and their corresponding fascial sheaths. The skin, muscles, and parietal peritoneum of the anterior abdominal wall are innervated by the lower six thoracic nerves and the first lumbar nerve. The anterior primary rami of these nerves exit their respective intervertebral foramina and extend over the vertebral transverse process. They then pierce the musculature of the lateral abdominal wall to travel through a neurofascial plane between the internal oblique and transversus abdominis muscles. Deposition of local anesthetic dorsal to the midaxillary line blocks both the lateral cutaneous branch and the lateral cutaneous afferents, thus facilitating blockade of the entire anterior abdominal wall. The transversus abdominis plane thus provides a space into which local anesthetic can be deposited to achieve myo-cutaneous sensory blockade.

This regional anesthesia technique has been shown to provide good postoperative analgesia for a variety of procedures involving the abdominal wall [91]. The use of a fine-gauge, blunt-tipped, short-bevel needle, and USG have been proposed to reduce the incidence of possible complications (intraperitoneal injection with bowel injury/ hematoma, liver laceration, transient femoral nerve palsy, accidental intravascular injection, infection, and catheter breakage). In addition, with US-guided techniques, upper and lower portions of the abdominal wall can be preferentially blocked [92].

**Peripheral Nerve Blocks for the Upper Extremities**

Severe trauma to the shoulders and arms is frequently present in acutely injured ICU patients. These injuries may be associated with blunt chest trauma requiring mechanical ventilation; they usually augment pain overall, especially during positioning [93]. If the orthopedic injury is part of complex trauma with closed-head injury causing alterations of mental status so that opioid-based analgesia regimens may mask the underlined neurologic condition, adequate analgesia can be provided with blocks of the brachial plexus. Continuous brachial plexus blocks consistently provide superior analgesia with minimal side effects, promoting earlier hospital discharge and possibly improving rehabilitation after major
surgery [94]. Peripheral nerve injury is a rare complication of regional anesthesia for the upper extremities. A large study from France reported 0.04% overall risk of a serious adverse event after peripheral nerve blockade [95]. Several retrospective studies reported the incidence to be between 0.5% and 1.0%, whereas prospective studies published higher incidence rates between 10% and 15% [96].

Current evidence suggests that peripheral nerve blockade should not be routinely performed in most adults during general anesthesia (GA) or heavy sedation especially when using the interscalene approach. However, the risk-to-benefit ratio of performing a peripheral nerve block under these conditions versus using high doses of opioids to maintain adequate analgesia should be carefully considered in select ICU patients [97]. Furthermore, the advent of USG techniques, in combination with injection pressure monitoring and nerve stimulation, may help to significantly minimize possible serious complications in heavily sedated patients with increased success rate and potential benefits overall.

Peripheral Nerve Blockade for the Lower Extremities

Lower extremity injuries are also commonly present in critically ill ICU patients. Reid et al. [98] recently conducted a study to compare the accuracy, success rates, and complications of USG femoral nerve blockade (FNBs) with the fascial pop technique in an emergency department. The result of this study favors the use of USG FNB. A similar study, conducted by Marhofer et al. [99] has demonstrated a clear benefit in the use of US over a peripheral nerve stimulator when performing a three-in-one nerve block. Use of both approaches (USG and peripheral nerve stimulation) may potentially improve the quality of the block, extend the duration, and provide better results with the use of smaller doses and less concentrated solutions of local anesthetic.

FNB is the preferred analgesic technique following injuries of the knee. Compared with epidural analgesia, it has a favorable morbidity profile, allows early mobilization, and there is no need for urinary catheterization. In addition, with USG, the technique is simple and easy to perform compared with the epidural blocks [100]. FNB and catheters are helpful in the management of acute pain following femoral fractures as well as after surgical stabilization [101].
Easy US-guided visualization of the sciatic nerve proximal to the popliteal fossa, before it divides into common peroneal nerve medially and tibial nerve laterally, makes the lateral approach to the sciatic nerve an ideal approach for management of pain secondary to distal tibia, ankle, and foot fractures [102]. This block can be conveniently performed in the supine position and enables more secure placement of a peripheral nerve catheter with high rates of success.

Epidural Analgesia

Epidural analgesia is the most frequently used regional anesthesia technique in the ICU [103] and has been reported to provide better pain relief than parenteral opioid administration [104]. However, there is conflicting evidence regarding a reduction of mortality with the use of epidural analgesia. The largest meta-analysis (CORTRA) to date and analysis of the Medicare claims database [105] associated a reduction in perioperative mortality with the use of perioperative neuraxial anesthesia. Procedure-specific meta-analyses and specific RCTs, however, have not demonstrated benefit from epidural anesthesia and analgesia regarding reduction in mortality. It is important to note that these specific meta-analyses and individual RCTs lack sufficient sample size due to the relatively low incidence of mortality (0.2% to 5%) overall [106].

A meta-analysis of more than 5,000 surgical patients [107] has shown that postoperative epidural analgesia reduces the time to extubation, length of ICU stay, incidence of renal failure, and morphine consumption during the first 24 hours after surgery, as well as maximal glucose and cortisol blood concentrations, and improves forced vital capacity. Many of these benefits may be relevant to ICU patients; they have been demonstrated to be beneficial in cardiac surgery [108] and thoracic trauma patients [109], as well as patients with severe acute pancreatitis [110].

Whether sepsis, with or without positive blood cultures, should be an absolute contraindication for the use of epidural analgesia is still a matter of debate [111]. In patients with ischemic heart disease, high TEA has been shown to improve systolic and diastolic myocardial function [112]. Data from a prospective randomized trial show that PCEA offers superior postoperative pain control after laparotomy for gynecologic surgery compared with traditional IV PCA [113].

TEA exerts a remarkable influence on the cardiovascular system. It reduces the risk of perioperative dysrhythmias except postoperative atrial fibrillation. In cardiac surgical patients, with decreased left ventricular function, the left ventricular global and regional wall motions are better preserved. TEA has also been associated with a reduction of cardiac
oxygen consumption without jeopardizing coronary perfusion pressure by increasing the diameter of stenotic coronary segments. As a result, TEA reduces the overall incidence of myocardial infarction. It produces functional hypovolemia by inhibiting the vasoconstrictor sympathetic outflow; moreover, it interferes with the integrity of renin–angiotensin system and increases vasopressin plasma concentration. Despite causing hypotension, TEA has a beneficial outcome during hemorrhagic shock [114].

Issues of consent, coagulopathy, and infection can be addressed easily in elective conditions; they become a major problem in patients with multiple trauma or extremely painful conditions.

A study published in Sweden reports the risk of hematoma with neuraxial anesthesia to be 1.3 to 2.7 per 100,000 [115]. The current recommendations of the American Society of Regional Anesthesia should be followed [116].

Placing epidural catheters safely and confirming the presence of an adequate sensory block can be difficult in critically ill, sedated, and anesthetized patients. Awake and cooperative patients usually facilitate the placement of an epidural catheter, minimizing the possibility of undesirable complications. Current recommendations suggest that the possibility to miss systemic local anesthetic toxicity under GA or heavy sedation is not a valid reason not to perform a neuraxial block in this group of patients. However, the indications for neuraxial regional anesthesia should be carefully considered when the procedure is to be performed in patients whose sensorium is compromised by GA or heavy sedation [97]. The overall risk of neuraxial anesthesia should be weighed against its expected benefit.

Positioning the patient for the procedure may also represent a challenge depending on the underlying injury and the number and position of tubes, catheters, or external fixation devices present. Strict asepsis should always be maintained for neuraxial procedures. Bolus injections of long-acting local anesthetics, such as bupivacaine and ropivacaine, or the discontinuation of continuous infusions every morning can help neurologic and sensory assessment.

The most common side effects of TEA are bradycardia and hypotension related to sympathetic blockade; this can be more pronounced with intermittent bolus dosing in patients with hypovolemia or shock. Continuous low-rate local anesthetic and/or opioid (morphine) infusions can be safely used in this particular clinical setting. Currently, sepsis and bacteremia are considered contraindications to neuraxial blockade. Fever and increased white blood cell count alone in the absence of positive blood cultures do not provide a reliable diagnosis of bacteremia. High levels of the serum markers C-reactive protein, procalcitonin, and interleukin-6/8 have been shown to indicate bacterial sepsis with a high
degree of sensitivity and specificity and can guide the decision as to whether or not to place an epidural catheter [117].

Because high-risk patients seem to profit most from epidural analgesia and the current literature does not address the specific problem of the critically ill patient with multiple comorbidities and organ failure, logic suggests that in carefully selected and closely monitored patients epidural analgesia may have significant benefits. Further research is needed before clear recommendations can be made.
INFLUENCE OF PAIN MANAGEMENT ON COMPLICATIONS, OUTCOMES, LENGTH OF HOSPITAL STAY, AND CHRONIC PAIN

A meta-analysis published in the year 2008 has concluded that epidural analgesia prevents postoperative major complications and may decrease postoperative mortality [77]. Other studies have reported that epidural anesthesia may selectively prevent the occurrence of respiratory and cardiovascular complications [118–120].

Conversely, other prospective trials have failed to confirm the beneficial effects of epidural anesthesia on postoperative morbidity and mortality after major abdominal or orthopedic surgery. Such a discrepancy is thought to be the result of overall improved postoperative medical care. As an example, a previously reported 50% reduction in DVT with epidural analgesia is no longer a valid criterion due to the recent introduction of low-molecular-weight heparin for management of DVT prophylaxis, which decreases the risk by more than 80%. Similarly, the use of prophylactic antibiotics and aggressive physiotherapy significantly reduces the postoperative pulmonary complications, and the preventive effect of epidural analgesia for chest infections has become less important. Consequently, there is no significant evidence to consider epidural analgesia beneficial for the prevention of morbidity, but as part of a multimodal pain management process, it may facilitate recovery after surgery and trauma. The superior quality of pain relief provided by epidural analgesia combined with parenteral analgesia does indeed have a positive impact on mobilization, bowel function, and early food intake with improvement in postoperative quality of life [121]. For orthopedic surgery patients, regional analgesia may provide functional benefits, allowing better patient involvement with physical therapy and shorter recovery time.

Improvements in perioperative outcomes following peripheral nerve block after major orthopedic surgery include significantly shorter hospital stay, earlier ambulation, improved joint range of motion, lower perioperative pain scores, and a reduction in postoperative nausea and vomiting. Patients treated with peripheral nerve blocks also had significantly lower opioid requirements when compared with controls, as well as significant reduction in urinary retention and postoperative ileus [122].

Although risk factors are difficult to identify, patients who experience severe pain and, above all, persistence of postoperative pain several days
after the expected duration are prone to develop chronic pain. Postoperative chronic pain is defined as persisting pain, without relapse or pain-free interval, 2 months after the surgical intervention. Chronic pain syndromes have been described commonly after breast surgery, inguinal hernia repair, cholecystectomy, thoracic surgery, cardiac surgery, and limb or organ amputation. The incidence has been recorded to be up to 60% [123]. With such a high incidence, it is very important to provide good postoperative and posttrauma pain control to prevent the occurrence of chronic pain syndromes.
CONCLUSIONS

Pain control in critically ill patients is of paramount importance. Achieving adequate levels of analgesia in trauma and surgery patients decreases the stress response and improves morbidity and mortality. Individual units and acute pain teams should employ pain assessment techniques for patients with impaired cognition.

Lack of education, fear of possible side effects, and inappropriate use of medications contribute to the ineffective treatment of pain in critically ill ICU patients. The expertise of pain management specialists and anesthesiologists is often necessary for the management of these complex situations.

Choosing the treatment plan that best fits the patient’s clinical conditions is mandatory. A potentially favorable outcome can be altered if inappropriate pain modalities are chosen and used.

A rational multimodal approach including the use of nonpharmacologic, pharmacologic, and regional analgesia techniques is desirable and often needed. The continued use of these techniques extended into the postoperative period may shorten recovery time and speed discharge.

Always assess and monitor the effects of a treatment modality on the patient’s pain and clinical conditions as well. Be prepared to make changes in therapy as needed.

Regional analgesia techniques (epidural and peripheral nerve blockade), although proved to be safe and effective, are underused in the management of pain in critically ill patients. They allow a decrease in the overall use of opioid analgesics and sedatives and reduce the possibility of developing potentially dangerous side effects. A correct indication, as well as an appropriate timing for their use, is required in order to increase their beneficial effects.

The availability of new technologies (e.g., ultrasonography) improves the quality and safety of upper and lower extremity peripheral nerve blocks even in heavily sedated ICU patients.

The most common indications for the use of neuromuscular blocking agents (NMBAs) in the intensive care unit (ICU) include emergency or elective intubations, optimization of patient–ventilator synchrony, management of increased intracranial pressure, reduction in oxygen consumption, and treatment of muscle spasms associated with tetanus. According to the American College of Critical Care Medicine and the Society of Critical Care Medicine clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient, these medications should be used only when all other means of optimizing a patient’s condition have been used. This recommendation is based on the concern that the administration of NMBAs may worsen patient outcome when administered during a course of critical illness, particularly if the patient is receiving systemic steroids at the same time [1]. However, this recommendation has recently been challenged. A prospective, multicenter, randomized study of 340 patients in the early stage of the acute respiratory distress syndrome (ARDS) demonstrated that use of cisatracurium for 48 hours was associated with improved survival without an increase in intensive care unit–acquired weakness (ICUAW) [2]. A retrospective cohort study examining several thousand mechanically ventilated patients with severe sepsis found that an early utilization of neuromuscular blockade was associated with lower mortality [3].

PHARMACOLOGY OF NMBAS

The neuromuscular junction (NMJ) consists of the motor nerve terminus, acetylcholine (ACh), and muscle end plate. In response to neuronal action
potentials, ACh is released from presynaptic axonal storage vesicles into the synapse of the NMJ. Both the presynaptic membrane and the postsynaptic end plate contain specialized nicotinic ACh receptors (nAChRs). The chemical signal is converted into an electric signal by binding of two ACh molecules to the receptor (αδ- and αε-subunits), causing a transient influx of sodium and calcium, and efflux of potassium from muscle cells. This depolarization propagates an action potential that results in a muscle contraction. Unbound ACh is quickly hydrolyzed in the synapse by the enzyme acetylcholinesterase to acetic acid and choline, thus effectively controlling the duration of receptor activation. A repolarization of the motor end plate and muscle fiber then occurs.
THE NICOTINIC ACETYLCHOLINE RECEPTOR

The nAChR is built of five subunit proteins, forming an ion channel. This ionic channel mediates neurotransmission at the NMJ, autonomic ganglia, spinal cord, and brain. During early development, differentiation and maturation of the NMJ and transformation of the nAChR take place: fetal nAChRs gradually disappear with the rise of new, functionally distinct, mature nAChRs.

These mature nAChRs (also termed adult, innervated, ε-containing) have a subunit composition of two α, β, ε, and δ in the synaptic muscle membrane. The only structural difference from the fetal nAChR is in substitution of the γ for the ε-subunit, although functional, pharmacologic, and metabolic characteristics are quite distinct. Mature nAChRs have a shorter burst duration and a higher conductance to Na⁺, K⁺, and Ca²⁺, and are metabolically stable with a half-life averaging about 2 weeks. The two α-, β-, δ-, and ε/γ-subunits interact to form a channel and an extracellular binding site for ACh and other mediators as well. As mentioned previously, simultaneous binding of two ACh molecules to αδ- and αε-subunits of an nAChR initiates opening of the channel and a flow of cations down their electrochemical gradient. In the absence of ACh or other mediators, the stable closed state (a major function of ε/γ-subunits) normally precludes channel opening [4].

Adult skeletal muscle retains the ability to synthesize not only adult, but also fetal (often called immature or extrajunctional)-type nAChRs. The synthesis of fetal nAChRs may be triggered in response to altered neuronal input, such as loss of nerve function or prolonged immobility, or in the presence of certain disease states. The major difference between fetal- and adult-type nAChRs is that fetal receptors migrate across the entire membrane surface and adult ones are mostly confined to the muscle end plate. In addition, these fetal nAChRs have a much shorter half-life, are more ionically active with prolonged open channel time that exaggerates the K⁺ efflux, and are much more sensitive to depolarizing agents such as succinylcholine and resistant to nondepolarizing neuromuscular blockers.

The functional difference between depolarizing and nondepolarizing neuromuscular blockers lies in their interaction with AChRs. Depolarizing neuromuscular blockers are structurally similar to ACh and bind to and activate AChRs. Nondepolarizing neuromuscular blockers are competitive antagonists.
DEPOLARIZING NEUROMUSCULAR BLOCKERS

Succinylcholine is the only depolarizing neuromuscular blocker in clinical use. Its use is limited to facilitating rapid-sequence intubation in the emergency setting. Succinylcholine mimics the effects of ACh by binding to the ACh receptor and inducing a persistent depolarization of the muscle fiber. Muscle contraction remains inhibited until succinylcholine diffuses away from the motor end plate and is metabolized by serum (pseudo-) cholinesterase. The clinical effect of succinylcholine is a brief excitatory period, with muscular fasciculations followed by neuromuscular blockade and flaccid paralysis. The intravenous dose of succinylcholine is 1 to 1.5 mg per kg and offers the most rapid onset of action (60 to 90 seconds) of the NMBAs. Recovery to 90% muscle strength after an intravenous dose of 1 mg per kg takes from 9 to 13 minutes.

Potential adverse drug events associated with succinylcholine include hypertension, arrhythmias, increased intracranial and intraocular pressure, hyperkalemia, malignant hyperthermia, myalgias, and prolonged paralysis. Neuromuscular blockade can persist for hours in patients with genetic variants of pseudocholinesterase isoenzymes. Contraindications to succinylcholine use include major thermal burns, significant crush injuries, spinal cord transection, malignant hyperthermia, and upper or lower motor neuron lesions. Caution is also advised in patients with open-globe injuries, renal failure, serious infections, near-drowning victims, and immobilization beyond 2 weeks.
NONDEPOLARIZING NMBAS

Nondepolarizing NMBAs function as competitive antagonists and inhibit ACh binding to postsynaptic nAChRs on the motor end plate. They are categorized into two classes on the basis of chemical structure: benzylisoquinolininiums and aminosteroids. Within each of these classes, the therapeutic agents may further be categorized as short-acting, intermediate-acting, or long-acting agents. The benzylisoquinolinium agents commonly used in the critical care setting include atracurium, cisatracurium, and doxacurium, whereas the aminosteroid agents include vecuronium, rocuronium, pancuronium, and pipecuronium.

The nondepolarizing NMBAs are administered by the intravenous route and have volumes of distribution ($V_d$) ranging from 0.2 to 0.3 L per kg in adults.

A clinical relationship exists between the time to onset of paralysis and neuromuscular blocker dosing, drug distribution, and ACh receptor sensitivity. An important factor to consider is $V_d$, which may change as a result of disease processes. Cirrhotic liver disease and chronic renal failure often result in an increased $V_d$ and decreased plasma concentration for a given dose of water-soluble drugs. However, drugs dependent on renal or hepatic excretion may have a prolonged clinical effect. Therefore, a larger initial dose but smaller maintenance dose may be appropriate.

Alterations in $V_d$ affect both peak neuromuscular blocker serum concentrations and time to paralysis. The pharmacokinetic and pharmacodynamic principles of commonly used NMBAs are summarized in Table 4.1.

### Atracurium

Atracurium is an intermediate-acting nondepolarizing agent. Neuromuscular paralysis typically occurs between 3 and 5 minutes and lasts 25 to 35 minutes after an initial bolus dose. Atracurium undergoes ester hydrolysis as well as Hofmann degradation, a nonenzymatic breakdown process that occurs at physiologic pH and body temperature, independent of renal or hepatic function. Renal and hepatic dysfunction should not affect the duration of neuromuscular paralysis. The

neuroexcitatory metabolite laudanosine is renally excreted. Laudanosine is epileptogenic in animals and may induce central nervous system excitation in patients with renal failure who are receiving prolonged atracurium infusions. Atracurium may induce histamine release after rapid administration.

Cisatracurium

Cisatracurium and atracurium are similar intermediate-acting nondepolarizing agents. A bolus dose of 0.2 mg per kg of cisatracurium usually results in neuromuscular paralysis within 1.5 to 2.5 minutes and lasts 45 to 60 minutes. When compared with atracurium, cisatracurium is three times as potent and has a more desirable adverse drug event profile, including lack of histamine release, minimal cardiovascular effects, and less interaction with autonomic ganglia. It also undergoes ester hydrolysis as well as Hofmann degradation. However, plasma laudanosine concentrations after cisatracurium administration are 5 to 10 times lower than those detected after atracurium administration.

Rocuronium

Rocuronium is the fastest onset, shortest acting aminosteroidal NMBA. A bolus dose of 0.6 mg per kg usually results in neuromuscular paralysis within 60 to 90 seconds. It may be considered an alternative to succinylcholine for rapid-sequence intubation at a higher dose (1.2 mg per kg). Rocuronium is primarily eliminated in the liver and bile. Hepatic or renal dysfunction may reduce drug clearance and prolong recovery time.

Vecuronium

An initial intravenous bolus dose of 0.1 mg per kg of vecuronium typically results in neuromuscular paralysis within 3 to 4 minutes and lasts 35 to 45 minutes. Vecuronium lacks vagolytic effects, such as tachycardia and hypertension, and produces negligible histamine release. Hepatic metabolism produces three active metabolites, the most significant being 3-desacetyl vecuronium, with 50% to 70% activity of the parent drug. Both vecuronium and its active metabolites are renally excreted. There is
potential for prolonged neuromuscular paralysis in patients with renal dysfunction receiving vecuronium by continuous infusion.

Pancuronium

Pancuronium is a long-acting nondepolarizing agent that is structurally similar to vecuronium. Unique features of pancuronium are its vagolytic and sympathomimetic activities and potential to induce tachycardia, hypertension, and increased cardiac output. Pancuronium is primarily excreted unchanged (60% to 70%) in the urine and bile, whereas the remaining 30% to 40% is hydroxylated by the liver to 3-hydroxy pancuronium. It has 50% activity of the parent drug and is renally eliminated. Renal dysfunction may result in the accumulation of pancuronium and its metabolites.

Doxacurium

Doxacurium is the most potent nondepolarizing agent available, but it has the slowest onset (as long as 10 minutes). It is practically devoid of histaminergic, vagolytic, or sympathomimetic effects. Doxacurium undergoes minimal hepatic metabolism, and excretion occurs unchanged in both the urine and the bile, with significantly prolonged effects seen in patients with renal dysfunction and, to a lesser extent, hepatic disease.

Pipecuronium

Pipecuronium is structurally related to pancuronium and its duration of action is 90 to 100 minutes, making it the longest acting NMBA. It is metabolized to 3-desacetyl pipecuronium by the liver, and both the parent compound and the metabolite are renally excreted. When compared with pancuronium, pipecuronium has a longer duration of action, less histamine release, and minimal cardiovascular effects.
REVERSAL AGENTS

The clinical effects of nondepolarizing neuromuscular blockers can be reversed by acetylcholinesterase inhibitors (anticholinesterases). These agents increase the synaptic concentration of ACh by preventing its synaptic degradation and allow it to competitively displace nondepolarizing NMBAs from postsynaptic nAChRs on the motor end plate. Because anticholinesterase drugs (e.g., neostigmine, edrophonium, and pyridostigmine) also inhibit acetylcholinesterase at muscarinic receptor sites, they are used in combination with the antimuscarinic agents (e.g., atropine or glycopyrrolate) to minimize adverse muscarinic effects (e.g., bradycardia, excessive secretions, and bronchospasm) while maximizing nicotinic effects. Typical combinations include neostigmine and glycopyrrolate (slower acting agents) and edrophonium and atropine (faster acting agents). The depth of neuromuscular blockade determines how rapidly neuromuscular activity returns [5]. Sugammadex is a new and novel agent (modified γ-cyclodextrin) that reverses rocuronium and other aminosteroid NMBAs by selectively binding and encapsulating the NMBA [6]. One of the advantages of sugammadex is the rapid reversal of the profound neuromuscular block, induced by the high dose of rocuronium needed for the rapid-sequence induction [7,8]—an effect that is equivalent to, if not better than, the spontaneous recovery from succinylcholine. Hence, rocuronium/sugammadex may prove to be an effective and safer alternative to succinylcholine in cases of the difficult airway and contraindications to the use of succinylcholine. Sugammadex is also useful as a reversal agent whenever the blockade is profound and there is an advantage for a timely reversal [8]. Sugammadex has been approved for use in Europe since 2008, but not in the United States. The initial nonapproval of the Food and Drug Administration (FDA) was based on concerns related to hypersensitivity and allergic reactions. However, a Cochrane systemic review concluded that sugammadex was not only effective but also equally safe when compared with placebo and neostigmine [9]. Sugammadex was finally approved for use in the United States in 2015. In addition to anaphylaxis, the FDA cautioned, in its approval statement, about marked bradycardia and cardiac arrest, observed within minutes of the administration of sugammadex.
A substantial number of medications commonly used in clinical practice have the potential for interaction with NMBAs. These interactions typically influence the degree and duration of clinical effects through either potentiation of or resistance to neuromuscular blockade. The most clinically relevant drug interactions with NMBA are discussed here and summarized in Table 4.2.

Potentiate blockade

Aminoglycosides and other antibiotics (e.g., tetracyclines, clindamycin, and vancomycin) have the ability to potentiate neuromuscular blockade and prolong the action of nondepolarizing agents through mechanisms including the inhibition of presynaptic ACh release, reduction in postsynaptic receptor sensitivity to ACh, blockade of cholinergic receptors, and impairment of ion channels. Penicillin and cephalosporin antibiotics do not interact with NMBAs and thus do not influence the degree of neuromuscular blockade.

Local, inhalational, and intravenous anesthetic and sedative agents may potentiate neuromuscular blockade. Local anesthetics reduce ACh release and decrease muscle contractions through direct membrane effects, whereas inhalational anesthetics desensitize the postsynaptic membrane and also depress muscle contractility.

Cardiovascular drugs such as furosemide, procainamide, quinidine, β-blockers, and calcium channel blockers have the ability to potentiate neuromuscular blocking effects. The role of the calcium ion in the release of ACh from vesicles into the synapse has been well established, although the exact interaction between calcium channel blockers and NMBAs
remains to be determined. Verapamil, a calcium channel blocker, has local analgesic effects and direct skeletal muscle effects, but its significance in drug interaction with NMBAs remains to be defined.

Chronic antiepileptic therapy, specifically phenytoin and carbamazepine, can increase the resistance to neuromuscular blocking effects, whereas the acute administration of phenytoin potentiates neuromuscular blockade. Chronic phenytoin therapy appears to induce an upregulation of ACh receptors, resulting in decreased postsynaptic sensitivity. Carbamazepine has been shown to induce resistance and shorten recovery times in combination with both pancuronium and vecuronium, possibly resulting from competition at the NMJ.
MONITORING OF NMBAS

Current guidelines recommend the routine monitoring of depth of neuromuscular blockade in critically ill patients [1]. It is important to remember that NMBAs have no analgesic and sedative effect. Careful clinical monitoring of the patient for signs consistent with inadequate sedation or analgesia—such as tachycardia, hypertension, salivation, and lacrimation—while receiving NMBAs is important. A recommendation to use monitors such as the Bispectral Index or the Patient State Index to ensure adequate depth of sedation while receiving NMBAs seems plausible; however, more studies are needed to determine whether these monitors are reliable and cost-effective in the critical care setting and whether they contribute to improved outcomes [10–12]. The modality of choice to monitor the depth of nondepolarizing neuromuscular blockade at present is train-of-four (TOF) monitoring. To determine the depth of blockade, four supramaximal stimuli are applied to a peripheral nerve (ideally, the ulnar nerve to assess an evoked response of the adductor pollicis muscle) every 0.5 seconds (2 Hz). Each stimulus in the train causes the muscle to contract, and “fade” in the response provides the basis for evaluation. To obtain the TOF ratio, the amplitude of the fourth response is divided by the amplitude of the first response. Before administration of a nondepolarizing muscle relaxant, all four responses are ideally the same: the TOF ratio is 1:1. During a partial nondepolarizing block, the ratio decreases (fades) and is inversely proportional to the degree of blockade [13].

Three prospective clinical trials have examined the question whether the routine use of TOF monitoring in the ICU will increase the cost-effectiveness and decrease the incidence of prolonged neuromuscular weakness. TOF monitoring for vecuronium appears to improve the outcome and decrease the cost of therapy. However, these outcomes could not be demonstrated for the benzylisoquinolinium agents, atracurium, and cisatracurium [14–16].
ADVERSE EFFECTS OF DEPOLARIZING AND NONDEPOLARIZING NMBAS IN CRITICALLY ILL PATIENTS

Significant progress has been made in the recent past in our understanding of the changes in regulation and distribution of ACh receptors during a course of critical illness. The majority of patients hospitalized in an ICU will undergo postsynaptic upregulation of nAChRs due to immobility, upper and/or lower motor neuron lesions, and/or pharmacologic denervation (such as NMBAs and aminoglycoside antibiotics). As outlined previously, immature receptors are not confined to the NMJ proper, but can be found over the entire surface of skeletal muscle (Fig. 4.1). This will lead to increased sensitivity to depolarizing NMBAs and decreased sensitivity to nondepolarizing NMBAs. Furthermore, these changes in receptor distribution and physiology put the patient at a heightened risk of succinylcholine-induced hyperkalemia. This is based on the fact that immature (fetal) nAChRs are low conductance channels with prolonged opening times and significantly higher potassium efflux into the systemic circulation as compared to mature (adult) nAChRs. Furthermore, succinylcholine is metabolized more slowly as compared to ACh, thus prolonging the “open” state of the immature receptors. Although upregulation of receptors during periods of immobilization has been described as early as 6 to 12 hours into the disease process, clinical studies suggest that succinylcholine-induced hyperkalemia is unlikely to occur within 14 days of immobility [17]. In contrast, a reduction in the number of postsynaptic nAChRs will result in resistance to depolarizing and increased sensitivity to nondepolarizing NMBAs. For conditions associated with the potential for ACh receptor upregulation, see Table 4.3.
FIGURE 4.1 Schematic of the succinylcholine (SCh)-induced potassium release in an innervated (top) and denervated (bottom) muscle. In the innervated muscle, the systemically administered SCh reaches all of the muscle membrane, but depolarizes only the junctional (α1, β1, δ, ε) receptors because acetylcholine receptors (AChRs) are located only in this area. With denervation, the muscle (nuclei) expresses not only extrajunctional (α1, β1, δ, γ) AChRs, but also α7AChRs throughout the muscle membrane. Systemic succinylcholine, in contrast to acetylcholine released locally, can depolarize all of the upregulated AChRs, leading to massive efflux of intracellular potassium into the circulation, resulting in hyperkalemia. The metabolite of SCh, choline, and possibly succinylmonocholine can maintain this depolarization via α7AChRs, enhancing the potassium release and maintaining the hyperkalemia.

(From Martyn JA, Richtsfeld M: Succinylcholine-induced hyperkalemia in acquired pathologic states: etiologic factors and molecular mechanisms. Anesthesiology 104:158, 2006, with permission.)

INTENSIVE CARE UNIT–ACQUIRED WEAKNESS

ICUAW is a term used to describe all weaknesses developed in critically ill patients after the onset of illness and in the absence of any identifiable causes. ICUAW is further classified into three entities: critical illness polyneuropathy (CIP), critical illness myopathy (CIM), and critical illness neuromyopathy [18,19] (see Chapter 154). These conditions occur in up to 50% to 70% of patients meeting diagnostic criteria for the systemic inflammatory response syndrome as well as in patients immobilized and on mechanical ventilation for more than a week [20]. They manifest as limb weakness and difficulty in weaning from the mechanical ventilator. Nondepolarizing muscle relaxants of both classes, aminosteroids and benzylisoquinoliniums, have been associated with the development of these neuromuscular disorders [21]; however, the etiology appears to be multifactorial and includes alterations in microvascular blood flow in conditions of sepsis/systemic inflammatory response syndrome and the concomitant administration of corticosteroids [20]. There is evidence suggesting that high-dose corticosteroids have direct physiologic effects on muscle fibers, resulting in a typical myopathy with loss of thick-filament proteins. Atrophy and weakness are observed primarily in muscles of trunk and extremities, and functional denervation of muscle with NMBAs in conjunction with corticosteroid therapy seems to heighten the risk of myopathy [21]. Furthermore, both methylprednisolone and hydrocortisone antagonize nAChRs, possibly potentiating the effects of NMBAs [22]. A differential diagnosis of weakness in ICU patients is presented in Table 4.4.

Critical Illness Polyneuropathy

Electrophysiologic findings of CIP are consistent with a primary, axonal degeneration, resulting in reduction in amplitudes of the compound muscle action potential and sensory nerve action potential. Although several case reports have suggested that NMBAs are causative agents in the etiology of this disorder, prospective studies of CIP have not confirmed a correlation between the use of NMBAs, steroids, and CIP [23] (see Chapter 180).

Critical Illness Myopathy

CIM can occur in association with, or independently of, CIP. A group of several myopathies of critical illness is now thought to be part of the same syndrome; these include acute quadriplegic myopathy, critical care myopathy, acute corticosteroid myopathy, acute hydrocortisone myopathy, acute myopathy in severe asthma, and acute corticosteroid and pancuronium-associated myopathy [24]. The major feature of this syndrome is flaccid, diffuse weakness, involving all limb muscles and neck flexors, and often the facial muscles and diaphragm. As with CIP, this can result in difficulty to wean from the mechanical ventilator. The syndrome is more difficult to diagnose than CIP, and diagnostic evaluations include electrophysiologic studies, muscle biopsy, and
laboratory evaluations (plasma creatine kinase levels). Again, there is no
definitive evidence suggesting that NMBAs are causative agents for this
syndrome, but rather a component in a multifactorial etiology. However,
the incidence of CIP and CIM appears to be higher in ICUs where these
agents are more frequently used [25].

Although only limited data are available suggesting that CIP increases
ICU and hospital mortality in critically ill patients, CIP and CIM appear
to be important causes of increased morbidity during and after acute care
hospital stay [26] (see Chapter 180).
SUMMARY AND RECOMMENDATIONS

Although there is currently insufficient evidence to demonstrate an unequivocal link between the use of NMBAs and an increase in morbidity and mortality in critically ill patients, it seems prudent to perform a careful risk–benefit analysis prior to the administration of this class of drugs in the ICU setting. Recent evidence suggests that the early utilization of neuromuscular blockade in ARDS and severe sepsis may improve survival [2,3]. However, more prospective data are needed to identify proper indications, selection of agents, and doses in the ICU setting. Concomitant use of drugs predisposing patients for the development of ICUAW, like steroids and aminoglycoside antibiotics, should alert the clinician for the increased risk in this setting. Succinylcholine can subject patients who are immobilized with upper and lower motor neuron lesions or with burns to a markedly increased risk of succinylcholine-induced hyperkalemia, and should be avoided in the ICU whenever possible. For recommendations for the administration of NMBAs to ICU patients, please see Table 4.5.

### Table 4.5 Recommendations for Administration of Neuromuscular Blocking Agents (NMBAs) to ICU Patients

1. Develop, use, and document a standardized approach for administering and monitoring NMBA
2. Use NMBA only after optimizing ventilator settings and sedative and analgesic medication administration
3. Establish the indications and clinical goals of neuromuscular blockade, and evaluate at least daily
4. Select the best NMBA on the basis of patient characteristics:
   A. Use intermittent NMBA therapy with pancuronium, doxacurium, or other suitable agent if clinical goals can be met
   B. If continuous infusion is required and renal or hepatic dysfunction is present, select atracurium or cisatracurium, and avoid vecuronium
5. Use the lowest effective dose for the shortest possible time (<48 h if possible), particularly if corticosteroids are concomitantly administered
6. Administer adequate analgesic and/or sedative medication during neuromuscular blockade, and monitor clinically and by bispectral array EEG if available
7. Systematically anticipate and prevent complications, including provision of eye care, careful positioning, physical therapy, and DVT prophylaxis
8. Avoid the use of medications that affect NMBA actions. Promptly recognize and manage conditions that affect NMBA actions.

9. Adjust NMBA dosage to achieve clinical goals (i.e., patient–ventilator synchrony, apnea, or complete paralysis).

10. Periodically (i.e., at least once or twice daily) perform NMBA dosage reduction, and preferably cessation (drug holiday) if clinically tolerated, to determine whether neuromuscular blockade is still needed and to perform physical and neurologic examination.

11. Periodically perform and document a clinical assessment in which spontaneous respiration, as well as limb movement, and/or the presence of DTRs are observed during steady-state infusion and/or during dosage reduction/cessation. With deep blockade, muscle activity may be present only during dosage reduction/cessation.

12. Perform and document scheduled (i.e., every 4–8 h) TOF testing for patients receiving vecuronium NMBA and/or undergoing deep neuromuscular blockade (i.e., apnea or complete paralysis), and adjust dosage to achieve one-fourth or more twitches. If clinical goals cannot be met when one-fourth or more twitches are present during steady-state infusion, demonstrate one-fourth or more twitches during dosage reduction/cessation. Consider TOF testing in all patients.

DTR, deep tendon reflexes; DVT, deep venous thrombosis; EEG, electroencephalogram; TOF, train of four.
REFERENCES

This chapter presents guidelines for safe cerebrospinal fluid (CSF) aspiration for the emergency department or the intensive care physician. It also provides a basic understanding of the indications, techniques, and potential complications of these procedures.

Health care providers routinely and safely perform CSF aspiration procedures using equipment and sterile supplies readily accessible in most patient care areas. Most of those procedures are performed at the bedside using local anesthesia alone. Because it could be a painful and anxiety-provoking procedure, sedation may be required especially for children [1,2]. Radiographic imaging (fluoroscopy or ultrasound) can be helpful to provide adequate guidance for safe needle placement, particularly in the setting of anatomic variations, trauma, operative scars, congenital defects, body habitus, or degenerative changes. Fluoroscopy and myelography may be used for complicated lumbar and C1–C2 puncture. Computed tomography (CT) may be used for stereotactic placement of ventricular catheters. Although lumbar pucture is performed by many health care providers, clinicians should recognize the need for specialized equipment and training in selected cases of CSF aspiration.

CEREBROSPINAL FLUID ACCESS

Diagnostic Objectives

CSF analysis continues to be an important diagnostic tool in many diseases. The most common indication for CSF sampling is the suspicion of a cerebral nervous system (CNS) infection. CSF is also analyzed for the diagnosis of subarachnoid hemorrhage (SAH), demyelinating diseases,
leptomeningeal spread of neoplasms, and neurodegenerative conditions. CSF access is necessary for some neurodiagnostic procedures that require injection of contrast agents, such as myelography, cisternography, or ventriculoperitoneal shunt patency. CSF access for pressure recording and monitoring is also important for the diagnosis of normal-pressure hydrocephalus, idiopathic intracranial hypertension, and some acute intracranial insults.

CSF is an ultrafiltrate of plasma in which the brain and the spinal cord float. It is normally clear and colorless. Abnormalities of color and clarity can reflect the presence of cells, protein, hemosiderin, or bilirubin that indicates pathologic processes. The diagnostic tests performed on the aspirated sample of CSF depend on the patient’s age, history, and differential diagnosis. A basic profile includes glucose and protein values, a blood cell count with differential, Gram stain, and aerobic and anaerobic cultures.

CSF glucose depends on blood glucose levels and is equivalent to approximately 1/2 to 2/3 of the serum glucose, and slightly higher in neonates. Glucose is transported into the CSF via carrier-facilitated diffusion, and changes in spinal fluid glucose concentration lag blood levels by about 2 hours. Increased CSF glucose is nonspecific and usually reflects hyperglycemia. Hypoglycorrachia (abnormally low CSF glucose) can result from infections, inflammatory, or neoplastic meningeal disorders; it reflects increased glucose use by nervous tissue, pathogens, or leukocytes and inhibited transport mechanisms. Elevated lactate levels caused by anaerobic glycolysis in bacterial and fungal meningitis usually accompany hypoglycorrachia.

CSF protein content is usually less than 0.5% of that in plasma with an intact blood–brain barrier. Albumin constitutes approximately 75% of CSF protein, and immunoglobulin G (IgG) is the major component of the γ-globulin fraction. IgG freely traverses a damaged blood–brain barrier. Although often nonspecific, elevated CSF protein is an indicator of CNS pathology. There is a gradient of total protein content in the spinal CSF column, with the highest level normally found in the lumbar subarachnoid space at 20 to 50 mg per dL, followed by the cisterna magna at 15 to 25 mg per dL and the ventricles at 6 to 12 mg per dL. A value exceeding 500 mg per dL is compatible with an intraspinal tumor or spinal compression, causing a complete subarachnoid block, meningitis, or blood in the CSF [3]. Low protein levels are seen in healthy children younger than 2 years, pseudotumor cerebri, recent lumbar puncture, chronic CSF leak, acute water intoxication, and leukemia.
A normal CSF cell count includes no erythrocytes and a maximum of five leukocytes per milliliter. A greater number of leukocytes is normally found in children (up to 10 per mL, mostly lymphocytes). Pathologically, increased white blood cells are present in infection, inflammation, leukemia, and hemorrhage.

**Hemorrhage**

A *nontraumatic* SAH in an adult may result from a ruptured aneurysm. A paroxysmal severe headache described as “the worst-headache-of-my-life” or a “thunderclap headache” is the classic symptom of aneurysmal rupture, but atypical headaches reminiscent of migraine are not uncommon. In one systematic review [4], De Falco reported that sentinel headache occurred in 10% to 43% of SAH patients in the 2 weeks preceding the hemorrhage and seems to be caused by a minor leak of an aneurysm. Lumbar puncture can be helpful with such presenting headache when the head CT is normal.

SAH can cause acute obstructive hydrocephalus by intraventricular extension or obstruction to CSF resorptive mechanisms at the arachnoid granulations. The head CT demonstrates ventriculomegaly, which is best treated by CSF access and diversion using an external ventricular catheter.

A traumatic lumbar puncture presents a diagnostic dilemma, especially in the context of diagnosing suspected SAH. Differentiating characteristics include a decreasing red blood cell count in tubes collected serially during the procedure, the presence of a fibrinous clot in the sample, and a typical ratio of about 1 leukocyte per 500 to 1,000 red blood cells. Xanthochromia is more indicative of SAH and is quickly evaluated by spinning a fresh CSF sample and comparing the color of the supernatant to that of water, ideally using a spectrophotometer which significantly increases the sensitivity for xanthochromia detection. Spinal fluid accelerates red blood cell hemolysis, and hemoglobin products are released within 2 hours of the initial hemorrhage, creating the xanthochromia. Associated findings, such as a slightly depressed glucose level, increased protein, and an elevated opening pressure, are further suggestive of SAH.

**Infection**

CSF evaluation is the single most important aspect of the laboratory diagnosis of meningitis and encephalitis. The analysis usually includes a blood cell count with differential; protein and glucose levels; and Gram stain and cultures with antibiotic sensitivities. When tuberculosis or fungal meningitis is suspected, the fluid is analyzed by acid-fast stain,
India ink preparation, cryptococcal antigen, and culture in appropriate media. More extensive cultures are helpful for evaluation of the immunocompromised patient.

Immunoprecipitation tests to identify bacterial antigens for *Streptococcus pneumoniae*, group B streptococcus, *Haemophilus influenzae*, and *Neisseria meningitidis* (meningococcus) allow rapid diagnosis and early specific treatment. Polymerase chain reaction (PCR) testing can be performed on CSF for rapid identification of several viruses. PCR testing exists for herpes viruses, including herpes simplex, varicella zoster, cytomegalovirus, and Epstein–Barr virus, as well as for toxoplasmosis and *Mycobacterium tuberculosis* [5].

**Shunt Malfunction**

A ventriculoperitoneal shunt is the most commonly implanted system for CSF diversion. It consists of a ventricular catheter connected to a reservoir and valve mechanism at the skull and a catheter that passes in the subcutaneous soft tissue in the neck and anterior chest wall to the peritoneum. The distal tubing can be alternatively inserted in the jugular vein, the pleura, or even the bladder. Failure of the ventricular catheter may occur because of choroid plexus obstruction or cellular debris from CSF infection. Valve or distal tubing obstruction also occurs from cellular debris, from disconnection, poor CSF absorption, or formation of an intra-abdominal pseudocyst.

The clinical presentation of an obstructed shunt is variable. It may be slowly progressive and intermittent, or a rapid decline in mentation progressing into a coma. A CT should be performed immediately to determine ventricular size. Ventriculomegaly is a reliable indicator of a malfunctioning shunt; however, the head CT should be compared with previous studies because the ventricular system in a shunted patient is often congenitally or chronically abnormal.

Aspiration from the reservoir or valve system of a shunt can be performed to determine patency and collect CSF to diagnose an infection. This invasive procedure itself carries a risk of contaminating the system with skin flora, and the resultant shunt infection requires a lengthy hospitalization for shunt externalization, antibiotic treatment, and replacement of all hardware. Therefore, the necessity of and procedure for a shunt tap is best left to a neurosurgeon and should be performed very selectively. When shunt failure is a result of distal obstruction, aspiration of CSF may temper neurologic impairment and even be lifesaving until surgical revision is performed.

**Normal-Pressure Hydrocephalus**
Serial lumbar punctures or continuous CSF drainage via a lumbar subarachnoid catheter can be used as diagnostic tests to select patients who would benefit from a shunt for CSF diversion. The results have a positive predictive value if the patient’s gait improves. Lumbar CSF access may also be used for infusion tests, measurement of CSF production rate, pressure–volume index, and outflow resistance or absorption. Some studies suggest that these values are also predictive of therapeutic CSF diversion [6,7].

**Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)**

Pseudotumor cerebri affects young persons, often obese young women. It produces nonlocalizing symptoms and could cause severe visual loss if left untreated [8]. Etiologic factors include dural sinus and internal jugular venous thrombosis, head injury, vitamin A overdosage, tetracycline, oral contraceptives, and pregnancy.

Intracranial pressure (ICP) is elevated (up to 40 cm H₂O) without ventriculomegaly or intracranial mass lesions. CSF dynamics demonstrates an increase in outflow resistance. Serial daily lumbar punctures can be therapeutic, with CSF aspirated until closing pressure is within normal limits (<20 cm H₂O), thus restoring the balance between CSF formation and absorption in some cases; other treatments include acetazolamide, diuretics, glycerol, steroids, and weight loss. If all these therapeutic interventions fail, placement of a permanent shunting system may be necessary.

**Neoplasms**

The subarachnoid space can be infiltrated by various primary or secondary tumors, giving rise to symptoms of meningeal irritation. CSF cytology can often but not always determine the presence of neoplastic cells. Systemic neoplasms, such as melanoma or breast cancer, have a greater propensity to metastasize into the CSF spaces than do primary CNS tumors and may even present primarily as meningeal carcinomatosis. Hematopoietic cancers such as acute leukemias and lymphoma also frequently infiltrate the subarachnoid spaces with little or no parenchymal involvement. Ependymoma, medulloblastoma, germinoma, and high-grade glioma are the most commonly disseminated primary tumors. CSF sampling is useful as an initial diagnostic and as a screening tool in the neurologically intact patient who harbors a tumor type with a high risk of CNS relapse. Lymphoma cells in primary CNS lymphoma are present in increased numbers, and pleocytosis correlates
with positive cytology [9]. A generous amount of CSF or multiple samples may be required for diagnosis. Cisternal puncture may enhance the diagnosis if the lumbar CSF is nondiagnostic.

Myelography

Lumbar puncture is the most common access for lumbar and cervical myelography because the density of contrast material is higher than CSF and may be directed by gravity to the area of interest. Cervical C1–C2 puncture can be used for access; however, owing to its high risk and complications, it is often reserved for patients for whom a successful lumbar puncture is not possible.

Other Neurologic Disorders

There is extensive literature on CSF changes in demyelinating diseases, including multiple sclerosis. Typical lumbar puncture findings are normal ICP, normal glucose levels, mononuclear pleocytosis, and elevated protein levels because of increased endothelial permeability. Immunoelectrophoresis reveals elevated IgG and oligoclonal bands that suggest inflammation in the CNS [10,11].

CSF findings described in other disease states include elevated \( \tau \) protein and decreased \( \beta \)-amyloid precursor protein in Alzheimer disease and the presence of anti-GM1 antibodies and cytoalbumin dissociation in Guillain–Barré syndrome [12].

Therapeutic Interventions

Fistulas

CSF leaks occur because of a variety of traumatic and nontraumatic etiologies. Orthostatic headache is a characteristic symptom, and rhinorrhea may be evident. Postoperative CSF leaks may complicate surgery at the skull base. Fistulas following middle cranial fossa or cerebellopontine angle surgery occur infrequently, and CSF usually leaks through the eustachian tube to the nasopharynx. Following suboccipital craniectomy, a fistula can result in a pseudomeningocele, which manifests as subcutaneous swelling at the incision site because dural closure in the posterior fossa is often difficult and not watertight. Leaks following lumbar surgery are unusual, but may occur as a result of recent
myelography, dural tear, or inadequate dural closure [13]. In children, repair of meningoceles or other spina bifida defects is more likely to present with a CSF leak because of dural or fascial defects.

The most common presentation of a CSF fistula follows trauma. Basilar skull fractures that traverse the ethmoid or frontal sinuses can cause CSF rhinorrhea. Fractures along the long axis of the petrous bone usually involve the middle ear, causing the hemotympanum or CSF otorrhea if the tympanic membrane is ruptured. Most CSF leaks present within 48 hours, but delayed leaks are not uncommon because the fistula can be temporarily occluded with adhesions, hematoma, or herniated brain tissue.

The diagnosis of a leak may be easily made on clinical examination; however, at times, the nature of a “drainage fluid” is uncertain, and laboratory characterization is necessary. Testing the fluid for glucose can be misleading because nasal secretions contain glucose. A chloride level often shows a higher value than in peripheral blood, but identification of $\beta_2$-transferrin is the most accurate diagnostic for CSF. This protein is produced by neuraminidase in the brain and is uniquely found in the spinal and perilymph fluids [14].

Elevation of the patient’s head is the primary treatment of CSF leak. Placement of a lumbar drainage catheter or daily lumbar punctures should be considered when conservative therapy fails. The use of a continuous lumbar drainage by a catheter is somewhat controversial because of the potential for intracranial contamination from the sinuses if the ICP is lowered. To help prevent such complications, the lumbar drain collection bag can be maintained no lower than the patient’s shoulder level and the duration of drainage should not exceed 5 days.

**Intracranial Hypertension**

Intracranial hypertension can cause significant neurologic morbidity or even death. There are multiple etiologies which include cerebral edema that surrounds tumors, intracranial hematomas, stroke, traumatic contusions, following cranial surgery, or radiation therapy. Diffuse brain swelling also occurs in the setting of inflammatory and infectious disorders such as Reye syndrome or meningitis, or as a result of hyperthermia, carbon dioxide retention, or intravascular congestion. Access to the intracranial CSF space can be useful for diagnosis and treatment [15]. A ventriculostomy is commonly used as an ICP monitor and to treat by CSF drainage. An ICP-measuring device should be placed following traumatic brain injury for patients who exhibit a Glasgow Coma Scale score less than 8, a motor score less than 6 (for patients who are not aphasic), and have initial CT findings of diffuse brain edema, intercranial hematoma, cortical contusions, or absent or compressed basal cisterns.
Other indications for ICP monitoring include cerebrovascular diseases, including aneurysmal SAH; ischemic and hypoxic cerebral insults; and intraparenchymal and intraventricular hemorrhage. Obstructive hydrocephalus is another major indication for placement of a ventricular catheter.

**Drug Therapy**

CSF can be a route of administration for medications such as chemotherapeutic agents and antibiotics in disease processes such as lymphoma, leukemia, meningeal carcinomatosis, meningitis, and ventriculitis. Agents may be infused intrathecally through a lumbar route or an intraventricular injection via an implanted reservoir. Serial injections of small amounts are performed to minimize neurotoxicity. Careful selection of the agent, dose, and timing of administration is recommended, especially when the ventricular route is used, because many antibiotics can cause seizures or inflammatory ventriculitis when given intrathecally.

**Thrombolytic Therapy in Intraventricular Hemorrhage**

Intraventricular hemorrhage causing obstructive hydrocephalus in the setting of intracranial hemorrhage or aneurysmal SAH is indicative of poor outcome. External ventricular drain (EVD) placement is a standard procedure in such settings to monitor ICP and drain CSF. Therapy with low-dose recombinant tissue plasminogen activator given through the EVD has been shown to facilitate clot resolution in the ventricular system. Studies are being carried out to establish the relation of such treatment on longer term outcomes [17–19].

**Lumbar Drainage in Thoracoabdominal Aortic Surgery**

One of the most common and grave complications of thoracoabdominal aortic surgery is paraplegia. It usually results from spinal cord ischemia and spinal cord swelling in the setting of perioperative hypotension and compromise of segmental arteries supplying the spinal cord, the largest of which is the artery of Adamkiewicz. Many techniques have been developed to decrease the risk of such complication. Among those techniques is prophylactic lumbar CSF drainage which decreases the CSF pressure, thereby increasing the spinal cord perfusion pressure. There are growing data which demonstrate that this technique decreases the incidence of paraplegia in both open and endovascular aneurysm repairs [20,21].
TECHNIQUES OF CEREBROSPINAL FLUID ACCESS

There are several techniques for CSF aspiration. All procedures should be performed using sterile technique (including sterile gloves and a mask), and the skin is prepared with antiseptic solution and draped with sterile barriers.

Lumbar Puncture

Lumbar puncture is the common technique to aspirate CSF. Contraindications to lumbar puncture include skin infection at the entry site, anticoagulation or blood dyscrasias, papilledema in the presence of supratentorial masses, posterior fossa lesions, and known spinal subarachnoid block or spinal cord arteriovenous malformations. Hence, it should not be performed without prior CT if the patient has any focal neurologic deficit, or a depressed mental status, because this might indicate the presence of an intracranial mass lesion or brain edema, and lumbar puncture can increase the likelihood of downward transtentorial herniation.

In adults, lumbar puncture is often performed under local anesthesia using 1% lidocaine alone. In the pediatric population, however, sedation is often required and allows for a better-tolerated procedure. This is also true in the case of anxious, confused, or combative adult patients.

Oral or rectal chloral hydrate may be used in small children, and moderate sedation using intravenous midazolam, ketamine, fentanyl, or dexmedetomidine can be highly successful in appropriately monitored adults and children when performed by an experienced individual. The application of a topical anesthetic, such as lidocaine preceding injection, can also be useful. Conversely, it has been demonstrated in a controlled clinical trial that in the neonatal population, injection of a local anesthetic for lumbar puncture is probably not required and does not reduce perceived stress or discomfort [22].

Figures 5.1 and 5.2 depict some of the steps for lumbar puncture. The patient is placed in the lateral knee-chest position or with the patient sitting leaning forward over a bedside table. The sitting position may be preferred for obese patients in whom adipose tissue can obscure the midline or in elderly patients with significant lumbar degenerative disease. Following a time-out (correct patient, procedure, site, and equipment), the local anesthetic is injected subcutaneously using a 25- or 27-gauge needle. A 1.5-inch needle is then inserted through the skin.
wheal and additional local anesthetic is injected along the midline, thus anesthesizing the interspinous ligaments and muscles. This small anesthetic volume is usually adequate; however, a more extensive field block is accomplished by additional injections on each side of the interspinous space near the lamina [23].

**FIGURE 5.1** Patient in the lateral decubitus position with back on the edge of the bed and knees, hips, back, and neck flexed.

**FIGURE 5.2** Patient sitting on the edge of the bed leaning on bedside stand.
The point of skin entry is midline at the level of the superior iliac crests, which is usually between the spinous processes of L3 to L4. Lower needle placement at L4 to L5 or L5 to S1 is required in children and neonates to avoid injury to the conus medullaris, which lies more caudal than in adults. The needle is advanced with the stylet in place to maintain needle patency and prevent iatrogenic intraspinal epidermoid tumors. The bevel of the needle should be parallel to the longitudinal fibers of the dura and spinal column. The needle should be oriented rostrally at an angle of about 30 degrees cephalad and virtually aimed toward the umbilicus. When properly oriented, the needle passes through the following structures before entering the subarachnoid space: skin, superficial fascia, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space with its fatty areolar tissue and internal vertebral plexus, dura, and arachnoid membrane (Fig. 5.3). The total depth varies from less than 1 inch in the very young patient to as deep as 4 inches in the obese adult. The kinesthetic sensations of passing through the ligaments into the epidural space followed by dural puncture are quite consistent and recognized with practice. Once intradural, the bevel of the needle is redirected in a cephalad direction in order to improve CSF flow. A spinal needle no smaller than 22 gauge should be used for pressure measurement. The opening pressure is best measured with the patient’s legs relaxed and extended from the knee-chest position. Pressure measurements may be difficult in children and may be estimated using CSF flow rate [24].
Once CSF is collected, the closing pressure is measured prior to needle withdrawal. It is best to replace the sterile stylet in the needle prior to exiting the subarachnoid space to prevent fistula formation. CSF pressure measurements are not accurate if performed in the sitting position because of the hydrostatic pressure of the CSF column above the entry point or if a significant amount of CSF was lost when the stylet is first withdrawn. If necessary, the pressure could be measured by reclining the patient to the lateral position once entry in the CSF space has been secured.

Although lumbar puncture is typically a safe procedure, there are a number of potential complications and risks involved. Among these complications, postural headache is the most common. Its reported frequency varies from 1% to 70% [25]. It is thought to be caused by excessive drainage of CSF or leakage into the paraspinal spaces, resulting in intracranial hypotension with stretching and expansion of the pain-sensitive intracerebral veins. Magnetic resonance imaging (MRI) has demonstrated a reduced CSF volume following lumbar puncture, but
with no significant brain displacement and no correlation with headache [26]. Psychologic factors and previous history of headaches seem to strongly influence the patient’s risk of and tolerance to headache [27]. A smaller needle size, parallel orientation to the dural fibers, a paramedian approach, and stylet reinsertion prior to withdrawal of the spinal needle have been reported to decrease the risk of headache after lumbar puncture [28]. The choice of needle type has been the subject of literature debate. Several needle tip designs are available, including the traditional Quincke needle with a beveled cutting tip, the Sprotte needle with a pencil point and side hole, and the Whitacre needle, which is similar to the Sprotte needle but with a smaller side hole. The use of an atraumatic needle seems to be adequate for the performance of a diagnostic lumbar puncture and is probably associated with a lower risk of a postpuncture headache [29]. Postdural puncture headache typically develops within 72 hours and lasts 3 to 5 days. Conservative treatment consists of bed rest, hydration, analgesics, and sometimes non-phenothiazine antiemetics if associated with nausea. If the symptoms are more severe, methylxanthines (caffeine or theophylline) are prescribed orally or parenterally. These agents are successful in up to 85% of patients [28,30]. If the headache persists, an epidural blood patch should be considered because it is one of the most effective treatments for this condition [31]. Epidural injection of other agents, such as saline, dextran, or adenocorticotropic hormone, has also been described and may be valuable under certain conditions (e.g., sepsis or immunodeficiencies).

Hemorrhage is uncommon but can be seen in association with bleeding disorders or anticoagulation therapy. Spinal SAH has been reported in such conditions, resulting in blockage of CSF outflow with subsequent back and radicular pain, sphincter disturbances, and even paraparesis [32]. Spinal subdural hematoma is likewise very infrequent, but it is associated with significant morbidity that may require prompt surgical intervention. Infection by introduction of the patient’s skin flora or the operator’s mouth or nose flora into the subarachnoid spaces, causing meningitis, is uncommon and preventable if aseptic techniques are used.

An uncommon sequela of lumbar puncture or continuous CSF drainage is hearing loss. Drainage decreases ICP, which is transmitted to the perilymph via the cochlear aqueduct and can cause hearing impairment [33]. The rate of occurrence of this complication is reported to be 0.4%, but is probably higher because it goes unrecognized and seems reversible. There are a few documented cases of irreversible hearing loss [34].

Transient sixth-nerve palsy has also been reported, probably because of nerve traction following significant CSF removal. Neurovascular injury can occur uncommonly in the setting of a subarachnoid block as a result of spinal tumors. In this situation, CSF drainage leads to significant traction and spinal coning with subsequent neurologic impairment
Utility of Ultrasonography for Performance of Lumbar Puncture

Ultrasonography has useful application for performance of lumbar puncture. In patients with standard anatomy, the use of ultrasonography does not offer advantage when compared with standard landmark technique [37]. However, ultrasonography has utility for guidance of lumbar puncture when patient-specific factors such as obesity or edema make it difficult to palpate the spinal processes or the midline of the lumbar region. In this case, the use of ultrasonography increases success rate and reduces the number of attempts required for obtaining the CSF sample [38,39].

With the patient in standard position for lumbar puncture, the operator uses a high-frequency vascular probe to scan the lumbar area below the level of the superior iliac crests. With the probe perpendicular to the skin surface in longitudinal scanning plane, the sagittal section in midline allows identification of the adjacent spinous processes (Video 5.1). This allows visualization of the target interspace that is bounded by the spinal processes and the deeper interspinous ligament. The site is marked, the depth for needle penetration measured, and the angle of the transducer noted, because this defines the angle for needle penetration. If it is difficult to locate the spinal processes in the sagittal scanning plane, a transverse scanning plane may be used for initial identification of the midline, followed by rotation of the probe to longitudinal orientation for verification of target site. The lumbar puncture is performed with standard technique and without real-time needle guidance. The main difficulty in using ultrasonography to aid in lumbar puncture relates to image quality. The patients in greatest need of ultrasonography guidance are the obese; and, yet, the greater the obesity, the more difficult it is to obtain adequate image quality, because of attenuation of the ultrasonography signal. Despite this, ultrasonography has value in this patient population.

Lateral Cervical (C1–C2) Puncture

The C1–C2, or lateral cervical, puncture was originally developed for percutaneous cordotomy. It may be used for myelography or aspiration of CSF if the lumbar route is inaccessible. It is most safely performed with fluoroscopic guidance with the patient supine, the head and neck flexed, and the lateral neck draped. The skin entry point is 1 cm caudal and 1 cm dorsal to the tip of the mastoid process. The site is infiltrated with a local anesthetic, and the spinal needle is introduced and directed toward the
junction of the middle and posterior thirds of the bony canal to avoid an anomalous vertebral or posterior inferior cerebellar artery that may lie in the anterior half of the canal. The stylet should be removed frequently to check for CSF egress. When the procedure is performed under fluoroscopy, the needle is seen to be perpendicular to the neck and just under the posterior ring of C1. The same kinesthetic sensation is recognized when piercing the dura as in a lumbar puncture and the bevel is then directed cephalad in a similar manner. Complications of the lateral cervical puncture include injury to the spinal cord or the vertebral artery and irritation of a nerve root, causing local pain and headache.

Cisternal Puncture

A cisternal puncture provides CSF access via the cisterna magna when other routes are not possible. A preoperative lateral skull radiograph is performed to ensure normal anatomy. The patient is positioned sitting with the head slightly flexed. The hair is removed in the occipital region, and the area is prepared, draped, and infiltrated with lidocaine. The entry point is in the midline between the external occipital protuberance in the upper margin of the spinous process of C2 or via an imaginary line through both external auditory meati. The spinal needle is directed through a slightly cephalad course and usually strikes the occipital bone. It is then redirected more caudally in a stepwise manner until it passes through the atlanto-occipital membrane and dura, producing a “popping” sensation. The cisterna magna usually lies 4 to 6 cm deep to the skin; the needle should not be introduced beyond 7.0 to 7.5 cm from the skin to prevent injury to the medulla or the vertebral arteries. The procedure can be performed relatively safely in a cooperative patient because the cisterna magna is a large CSF space; however, it is rarely practiced owing to the greater potential morbidity.

Aspiration of Reservoirs and Shunts

An implanted reservoir or shunt system should not be accessed without prior consultation with a neurosurgeon, despite the apparent simplicity of the procedure itself. Violating implanted systems carries several risks, including infection, which can result in a lengthy hospitalization, prolonged antibiotic course, and several operative procedures for shunt externalization, hardware removal, and insertion of a new shunt system. Subcutaneous reservoirs in ventriculoatrial or ventriculoperitoneal shunting systems are located proximal to the unidirectional valve and can
be accessed percutaneously. The reservoirs are usually button sized, measuring approximately 7 to 10 mm in diameter and 2 mm in height. They can be located in the burr hole directly connected to the ventricular catheter (Fig. 5.4) or as an integral part of the valve system (Fig. 5.5). Indications for reservoir taps have been previously discussed.

**FIGURE 5.4** Close-up view of ventricular reservoir in the calvarial burr hole, with the funneled base connected directly to the proximal end of the ventricular catheter. The distal perforated end is shown.
The procedure can be performed in any hospital or outpatient setting using sterile techniques. The patient can be in any comfortable position that allows access to the reservoir. Sedation may be required for toddlers. Reference to a skull radiograph may be helpful in localization. The reservoir is palpated, overlying hair is removed with a clipper rather than a razor, and the skin cleansed. Local anesthesia is usually not required, and the use of topical anesthetic creams is occasionally considered. The needle is inserted perpendicular to the skin and into the reservoir, to a total depth of 3 to 5 mm. A manometer is then connected to the needle or butterfly tubing for pressure measurement. CSF collection or drug injection is performed only if CSF flow is demonstrated. A “dry tap” usually indicates faulty placement or catheter obstruction. Occasionally, an old reservoir may have retracted into the burr hole and not be palpable or may be too calcified for needle penetration, and some older shunting systems did not include a reservoir. Risks and complications of shunt aspiration include improper insertion, infection, introduction of blood in the shunt system, and choroid plexus hemorrhage caused by vigorous aspiration.

Lumboperitoneal Shunt

Lumboperitoneal shunts are placed via percutaneous insertion of a lumbar subarachnoid catheter or through a small skin incision. They are tunneled subcutaneously around the patient’s flank to the abdomen, where the distal catheter enters the peritoneal cavity through a separate abdominal incision. A reservoir or valve or both may be used and are located on the lateral aspect of the flank. Careful palpation between the two incisions usually reveals the tubing path and reservoir placement in the nonobese patient. The patient is placed in lateral decubitus position, and a pillow under the dependent flank may be of assistance. The same technique as described for a ventricular shunt is then performed. Fluid aspiration should be particularly gentle because an additional risk of this procedure is nerve root irritation.

Ventricular Reservoirs

Ventricular reservoirs are inserted as part of a system consisting of a catheter located in a CSF space, usually the lateral ventricle, and without distal runoff. Such systems are placed for CSF access purposes, such as for instillation of antibiotics or chemotherapeutic agents, or CSF
aspiration for treatment and monitoring. Ommaya reservoirs are dome-shaped structures (Fig. 5.6) with a diameter of 1 to 2 cm and have a connecting port placed at their base or side. They are placed subcutaneously and attached to a ventricular subarachnoid catheter (Fig. 5.7). Aspiration technique is essentially the same as from a shunt reservoir; however, the Ommaya reservoir is often larger and differs in shape from many shunt reservoirs. It is accessed, preferably, with a 25-gauge needle or butterfly. CSF is allowed to flow by gravity if possible; a volume equal to that to be instilled is removed and held for analysis or reinjection. The antibiotic or chemotherapeutic agent is injected; 1 mL of CSF or sterile saline can be used to flush the dose into the ventricle, or gentle barbotage of the reservoir may be performed. Risks and complications are essentially the same as in shunt aspirations (i.e., infection, bleeding, and improper insertion), with the addition of chemical ventriculitis or arachnoiditis.

**FIGURE 5.6** Close-up view of a ventricular (Ommaya) double-domed reservoir, the caudal half of which is designed to lie within the burr hole.
Ventriculostomy

A ventriculostomy is a catheter placed in the lateral ventricle for CSF drainage or ICP monitoring and treatment. It is performed by a neurosurgeon in the operating room or at the bedside in the intensive care unit or emergency department. It is usually performed through the nondominant hemisphere and into the frontal horn of the lateral ventricle. An alternate approach is to cannulate the occipital horn or trigone through an occipital entry point located 6 cm superior to the inion and 4 cm from the midline. Premedication is not necessary unless the patient is very anxious or combative. Radiographic guidance is typically not required unless the procedure is being performed stereotactically. CT or MRI stereotaxy is needed if the ventricles are very small, as in diffuse brain swelling or slit ventricle syndrome. Complications of ventriculostomy placement include meningitis or ventriculitis, scalp wound infection, intracranial hematoma or cortical injury, and failure to cannulate the ventricle.
Lumbar Drainage

Continuous CSF drainage via a lumbar catheter is useful in the treatment of CSF fistulas and as a diagnostic test to demonstrate the potential benefit of shunting in normal-pressure hydrocephalus. Commercially available lumbar drainage kits are closed sterile systems that drain into a replaceable collection bag. Catheter placement is performed just as in lumbar puncture; however, a large-bore Tuohy needle is used, through which the catheter is threaded once CSF return has been confirmed. Needle orientation follows the same guidelines as for lumbar puncture and is even more important in the case of this large-gauge needle. Epidural catheter kits could also be used, although the catheters tend to be slightly stiffer and have a narrower diameter. Complications are essentially the same as in lumbar pucture, with the addition of supratentorial subdural hematoma secondary to overdrainage, which tends to be more common in elderly individuals. The potential for overdrainage is significant because of the large diameter of the catheter and because the amount of drainage depends on the cooperation of the patient and the nursing staff. In order to minimize the chances of such a complication, specialized kits are available that provide volume-limiting CSF drainage and monitoring (LimiTorr, Integra Lifescience Corporation, Plainsboro, NJ). These kits can be used in ventricular and lumbar drainge catheter systems and utilize a valve that halts drainage when the predetermined volume (usually 20 or 30 mL) is reached (Fig. 5.8).
FIGURE 5.8 Volume-limiting CSF drainage system. It is attached to CSF collecting systems such as a lumbar drain to avoid overdrainage and subsequent complications, such as a supratentorial subdural hematoma. CSF, cerebrospinal fluid.
SUMMARY

CSF aspiration is a very important diagnostic and therapeutic tool for many disease processes. Of the various techniques available for CSF access, lumbar puncture is the procedure most commonly and safely performed by the critical care practitioner. Other techniques are described that may require the assistance of a radiologist, neurologist, anesthesiologist, or neurosurgeon.
REFERENCES

The art and science of central venous catheter (CVC) insertion, maintenance, and management continues to evolve. Increased emphasis on patient safety and prevention of nosocomial complications has focused attention on the impact of CVCs on patient health. Catheter-related infection (CRI), often with a resistant organism such as methicillin-resistant \textit{Staphylococcal aureus} or vancomycin-resistant \textit{enterococci}, remains an important cause of increased patient morbidity and mortality. All institutions are encouraged to adopt evidence-based protocols and procedures designed to reduce CRI and other catheter complications \cite{1}. Patient safety is also the main impetus for increased availability of simulation laboratories to train health care providers in the use of portable ultrasound to facilitate catheter insertion \cite{2,3}. With systematic training, including a clear description of the technique with video examples, hands-on simulation emphasizing visualization of the needle tip, and supervision by experienced clinicians, high-fidelity ultrasound-guided CVC placement can be a reliably acquired skill \cite{4}.

Because of the availability and relatively low cost of portable ultrasound units, many nonradiologists have been performing bedside image-guided central venous cannulation. Ultrasound guidance allows visualization of the vessel, thus showing its precise location and patency in real time. It is especially useful for patients with suboptimal body habitus, volume depletion, shock, anatomic deformity, previous cannulation, underlying coagulopathy, or prior intravenous (IV) drug abuse. The use of ultrasound guidance has significantly decreased the failure rate, complication rate, and the number of attempts in obtaining central venous access. Experts agree that ultrasound guidance should be standard of care for all CVC insertions \cite{4}. The Third Sonography Outcomes Assessment Program trial, a concealed, randomized, controlled multicenter study, demonstrated an odds ratio 53.5 times higher for success with ultrasound guidance compared with the landmark technique. It also demonstrated a significantly lower average number of attempts and average time of catheter placement \cite{5,6}. 
In this chapter, we review the techniques and complications of the various routes available for central venous catheterization, and present a strategy for catheter management that incorporates all of the recent advances.

INDICATIONS AND SITE SELECTION

Like any medical procedure, CVC has specific indications and should be reserved for the patient who has potential to benefit from it. After determining that CVC is necessary, the health care provider should seek the most appropriate site and route for that particular patient. Table 6.1 lists general priorities in site selection for different indications of CVC; however, the final choice of site in a particular patient should, in part, be based on the operator experience. We recommend that all internal jugular and femoral vein (FV) cannulations be performed under ultrasound guidance, with consideration of using ultrasound guidance for the subclavian vein (SCV) approach depending on the operator experience.

IJV and FV assume ultrasound guidance (see text for details).

ARDS, acute respiratory distress syndrome; AV, antecubital vein; CVP, central venous pressure; EJV, external jugular vein; FV, femoral vein; IJV, internal jugular vein; IV, intravenous; L, left; PICC, peripherally inserted central venous catheter; R, right; SCV, subclavian vein.

Volume resuscitation alone is not an indication for CVC. A 2.5-inch, 16-gauge catheter used to cannulate a peripheral vein can infuse twice the amount of fluid as an 8-inch, 16-gauge CVC [7]. However, peripheral vein cannulation may be very difficult in the patient with shock, and, hence, CVC placement may be necessary. Long-term total parenteral nutrition is best administered through a peripherally inserted central catheter (PICC) because these lines are associated with fewer severe complications and significant cost savings [8]. The internal jugular vein (IJV) is the preferred site for acute hemodialysis; the SCV should be avoided because of the relatively high incidence of subclavian venous stenosis following temporary dialysis. This, in turn, may limit options for an arteriovenous fistula should long-term dialysis become necessary [9]. The FV is also suitable for acute short-term hemodialysis or plasmapheresis in the nonambulatory patient. However, FV catheters have a higher rate of infection and are not recommended unless absolutely necessary [10–12]. When used, FV catheters should be removed as soon as possible.

Emergent transvenous pacemakers and flow-directed pulmonary artery catheters are best inserted through the right IJV because of the direct path to the right ventricle. This route is associated with the fewest catheter tip malpositions. The SCV is an alternative second choice for pulmonary artery catheterization even in many patients with coagulopathy [13]. The left SCV is preferred to the right SCV because of a less torturous route to the heart. The reader is referred to Chapter 19 for additional information on the insertion and care of pulmonary artery catheters.

Preoperative CVC placement is desirable in a wide variety of clinical
situations. One specific indication for preoperative right ventricular catheterization is the patient undergoing a posterior craniotomy or cervical laminectomy in the sitting position. These patients are at risk for air embolism, and the catheter can theoretically be used to aspirate air from the right ventricle, although data does not support the efficacy of this process [14]. Neurosurgical patients may benefit from the placement of an antecubital or a subclavian catheter, as opposed to IJV catheters. IJV catheters can theoretically obstruct blood return from the cranial vault potentially increasing intracranial pressure, although a small study suggests that venous return is not significantly reduced [15].

Venous access during cardiopulmonary resuscitation warrants special comment. Peripheral vein cannulation in circulatory arrest may prove impossible, and circulation times of drugs administered peripherally are prolonged when compared with central injection. Drugs injected through femoral catheters also have a prolonged circulation time, although the clinical significance is unclear [16]. Effective drug administration is a very important element of successful cardiopulmonary resuscitation, and all physicians should understand the appropriate techniques for establishing access. If venous access is not readily available, placement of an intraosseous device has been shown to be more efficient in establishing access, equivalent in pharmacokinetic studies and is considered the standard alternative to IV access [17].

The placement of CVC is common in patients with severe sepsis, septic shock, or acute respiratory distress syndrome. However, the necessity of CVC placement has been minimized in recent years, perhaps in part, to the ARISE, PROMISE, and ProCess trials, which showed no difference between early goal-directed therapy and what has become the standard of care. Thus, fewer central lines may be placed because of fewer indications for frequent monitoring of central venous oxygen saturations and central venous pressures [18,19].
GENERAL CONSIDERATIONS

General considerations for CVC independent of the site of insertion include the need for signed informed consent, ensuring patient comfort and safety, and ultrasound preparation. Determining the presence of coagulopathies, and prevention of complications such as vascular erosions, catheter-associated thrombosis, and air embolism, is also important.

Informed Consent

It seems intuitively obvious that a signed informed consent is mandatory before nonemergent CVC insertion, but, in clinical practice, many emergent insertions are required. CVC insertions in the ICU are extremely common, occur at all hours of the day, and may be crucial for early and appropriate resuscitation and commencement of care. Many critically ill patients have no immediately available family members or legal next of kin. Obtaining informed consent for these patients can prevent or delay the delivery of life-saving therapies. Because of these considerations, there is no uniform clinical or legal opinion regarding the necessity of individual informed consent prior to all CVC insertions or other ICU procedures [20]. Some institutions have dealt with this matter by developing a single general “consent form for critical care” that is signed one time for each individual ICU admission and covers all commonly performed bedside procedures. Up to 14% of all ICU included in a survey study used such a consent form, and overall consent practice varied widely. In general, health care providers in medical ICUs sought consent for CVC insertion more often than those in surgical ICUs [20].

Given the lack of agreement on this topic, it seems prudent to make a few recommendations: (1) Written informed consent should be obtained prior to all elective CVC insertion or other procedures. (2) Whenever possible, competent patients or legal next of kin of incompetent/incapacitated patients should be thoroughly informed of the indications, risks, and benefits of emergency CVC insertion prior to the performance of the procedure. If informed consent is not possible prior to CVC insertion, then consent should be obtained as soon as possible after completion of the procedure. A signed consent form is always preferable, but sometimes not feasible. Oral consent should be documented in the procedure note by the person obtaining assent. (3) Emergent CVC placement should not be delayed inappropriately by efforts to obtain consent—oral or written. Patients and family should be informed as soon as possible after insertion why the CVC was required. (4) A general
consent form that is signed one time as close as possible to ICU admission is a reasonable way to try and inform patients of the benefits/risks of procedures without incurring unnecessary delays or consumption of clinical time. This form can also serve as a useful reference for patients and families of all the various common procedures that are performed in the ICU. (5) Finally, it is good practice to document the practice that is used in the institution’s “Policies, Guidelines, and Procedures” along with the rationale for it [21].

Patient Comfort and Safety

Many patients requiring CVC have an unstable airway, are in respiratory distress, or are hemodynamically unstable. These patients may not tolerate lying flat for CVC placement. Patients with unstable airways or respiratory distress frequently require addressing their respiratory status prior to placing a CVC. These considerations should impact preparation and choice of site. In addition, many patients are claustrophobic and will not tolerate their face being covered. Every patient should be specifically assessed prior to CVC regarding their positioning, airway, and hemodynamic stability. Once the patient is stabilized, the appropriate site/catheter can then be inserted under less unstable/rigorous conditions.

Mobile Catheter Cart

Availability of a mobile catheter cart that contains all necessary supplies and that can be wheeled to each patient’s bedside is good practice and likely reduces overall catheter infection rate by decreasing breaks in sterile technique [23]. The mobile cart is also an excellent way to standardize all catheter insertions, facilitate communication of procedural tasks (such as the use of a time-out), and allow for optimal documentation.

Catheter Tip Location

Catheter tip location is a very important consideration in CVC placement. The ideal location for the catheter tip is the distal innominate or proximal superior vena cava (SVC), 3 to 5 cm proximal to the cavotrial junction. Positioning of the catheter tip within the right atrium or right ventricle should be avoided. Cardiac tamponade secondary to catheter tip perforation of the cardiac wall is uncommon, with two-thirds of patients suffering this complication die [24]. Perforation likely results from vessel wall damage from infused solutions combined with catheter tip migration that occurs from the motion of the beating heart as well as patient arm and neck movements. Although not often considered, catheter tips can
migrate up to 5 to 10 cm with antecubital catheters and 1 to 5 cm with IJV or SCV catheters [25]. Other complications from intracardiac catheter tip position include provocation of arrhythmias from mechanical irritation [26].

Correct placement of the catheter tip is relatively simple, beginning with an appreciation of anatomy. The cavoatrial junction is approximately 16 to 18 cm from right-sided skin punctures and 19 to 21 cm from left-sided insertions and is relatively independent of patient gender and body habitus [27]. A chest radiograph should be obtained following every initial CVC insertion to ascertain catheter tip location and to detect complications. The right tracheobronchial angle is the most reliable landmark on plain chest radiograph for the upper margin of the SVC, and is always at least 2.9 cm above the cavoatrial junction. The catheter tip should lie about 1 cm below this landmark, and above the right upper cardiac silhouette to ensure placement outside the pericardium [28].

Vascular Erosions

Large-vessel perforations secondary to CVCs are very rare, about 0.28 per 1,000 catheter days and occur on average between days 5 and 8 after insertion. Symptoms included dyspnea, chest pain, and palpitations. Radiographically, a pleural or pericardial effusion may be seen. This complication is more common in older patients and left-sided catheters and is considered to be related to the angle of the catheter tip adjacent to the superior vena cava [29]. Treatment should include removal of the catheter and symptomatic management of subsequent complications that arise, including possible thoracentesis, pericardiocentesis or chest tube placement. Additionally, given the significant morbidity and mortality associated with this complication, we would suggest consideration of a vascular surgery consultation [30].

Complications

Venous Air Embolism

Venous air embolism (VAE) is rare and preventable potentially life-threatening complication of CVC placement. As little as 200 mL of air has been theorized to cause a fatal embolism [31]. VAE often goes undiagnosed, leading to a fatal outcome. Potential mechanisms include air entry through the needle during placement, catheter disconnection
resulting in the catheter being open to the atmosphere, and, more commonly, passage of air through a patent tract after catheter removal. Placing the patient in Trendelenburg (thereby increasing venous pressure) during catheter placement and removal will reduce this complication. VAE should be suspected in any patient with an indwelling or recently discontinued CVC who develops sudden unexplained hypoxemia or cardiovascular collapse. Often, VAE occurs after movement or when the patient is transferred out of bed. A characteristic mill wheel sound may be auscultated over the precordium. VAE can be confirmed with a bedside cardiac ultrasound. If VAE is found, the patient should be placed in the Trendelenburg and left lateral decubitus positions. This may trap the air in the apex of the right ventricle and prevent pulmonary artery outflow obstruction. Theoretically, a CVC can be used to aspirate the air from the right ventricle; this is rarely feasible [14]. The best treatment is prevention which can be effectively achieved through comprehensive nursing and physician-in-training educational modules and proper supervision of inexperienced operators [5,14,32].

Coagulopathy

Central venous access in the patient with a bleeding diathesis can be problematic. The SCV and IJV routes have increased risks in the presence of coagulopathy, but the true risk is frequently overestimated and it is not known at what degree of abnormality it becomes unacceptable. A coagulopathy is generally defined as an international normalized ratio greater than 1.5 or platelet count less than 50,000 per μL. Recently, studies have shown that we likely overestimate the increased risk of bleeding even with the subclavian approach and that ultrasound-guided IJV is safe even with significant coagulopathy. However, it is prudent to attempt to correct the coagulopathy and to favor a more compressible site, such as the IJV or FV, over the subclavian approach [33].

Thrombosis

Catheter-related thrombosis is common but usually of little clinical significance. The spectrum of thrombotic complications includes a fibrin sleeve surrounding the catheter from its point of entry into the vein distal to the tip; mural thrombus, a clot that forms on the wall of the vein secondary to mechanical or chemical irritation; or occlusive thrombus, which blocks flow and may result in collateral formation. All of these lesions are usually clinically silent; therefore, studies that do not use venography or color-flow Doppler imaging to confirm the diagnosis underestimate its incidence. However, the incidence may be as high as two-thirds of patients with CVC and underlying malignancy. In contrast,
clinically overt symptoms of thrombosis occur between 5% and 25%. Infrequently, CVC-related upper extremity deep vein thromboses increase the risk of pulmonary embolism, with estimates ranging from 2% to 9% [34,35]. The presence of catheter-associated thrombosis is, however, associated with a higher incidence of infection [36]. If a CVC-associated thrombus is found, the catheter should be removed, and consideration for systemic anticoagulation should be entertained.

Infectious Complications

There are an estimated 18,000 cases of ICU central line–associated bloodstream infection annually in the United States [37]. Many factors impact the risk of developing these infections, including insertion technique, site, daily care, and type of catheter used. Table 6.2 summarizes current recommendations or interventions that have been shown to reduce the risk of CRI. A complete review of CRIs can be found in Chapter 79.

TABLE 6.2 Steps to Minimize Central Venous Catheterization (CVC)–Related Infection

1. Institution-supported standardized education, with knowledge assessment, of all physicians involved in CVC insertion and care
2. Site preparation with approved chlorhexidine-based preparation
3. Maximal barrier precautions during catheter insertion
4. Use of mobile procedure carts, safety checklist, empowerment of staff
5. Strict protocols for catheter maintenance (including bandage and tubing changes), preferably by dedicated IV catheter team
6. Appropriate site selection, avoiding heavily colonized or anatomically abnormal areas; use of SCV for anticipated CVC of >4 d
7. For anticipated duration of catheterization exceeding 96 h, use of silver-impregnated cuff, sustained release chlorhexidine gluconate patch, and/or antibiotic/antiseptic-impregnated catheters
8. Prompt removal of any catheter which is no longer required
9. Remove pulmonary artery catheters and introducers after 5 d
10. Replace any catheter not placed with sterile precautions within 48 h (i.e., catheter placed in emergency)
11. Use multilumen catheters only when indicated; remove when no longer needed
12. Avoid “routine” guidewire exchanges
.3. Use surgically implanted catheters or PICCs for long-term (i.e., >3 wk) or permanent CVC

IV, intravenous; PICC, peripherally inserted central catheter; SCV, subclavian vein.
ROUTES OF CENTRAL VENOUS CANNULATION

In this section, the anatomy of the various approaches to achieving central venous access is described first, followed by how to achieve access using ultrasonography.

Antecubital Approach

The antecubital veins are used in the ICU for CVC with PICC and midline catheters. Specialized nursing teams are able to insert PICCs at beside with the use of real-time ultrasonography and sterile technique, thereby increasing safety and reducing the potential for infection. PICCs may be useful in ICU patients undergoing neurosurgery, with coagulopathy, or in the rehabilitative phase of critical illness for which general-purpose central venous access is required for parenteral nutrition or long-term medication access [38] (Table 6.1). Although many hospitals have a designated “PICC” insertion team, they may have significant work hour limitations that delay insertion of catheters and result in significant delays in delivery of care.

Anatomy

The basilic vein is preferred for CVC placement because it is almost always of substantial size and the anatomy is predictable. It provides an unimpeded path to the central venous circulation via the axillary vein and is formed at the ulnar aspect of the dorsal venous network of the hand. It may be found in the medial part of the antecubital fossa, where it is usually joined by the median basilic vein. It then ascends in the groove between the biceps brachii and pronator teres on the medial aspect of the arm to perforate the deep fascia distal to the midportion of the arm, where it joins the brachial vein to become the axillary vein.

Technique of Cannulation

Several kits are available for antecubital CVC. The PICC and midline catheters are made of silicone or polyurethane and, depending on
catheter stiffness and size, are usually placed through an introducer. The method described below is for a PICC inserted through a tear-away introducer.

The success rates from either arm are comparable, although the catheter must traverse a greater distance from the left. With the patient’s arm at his or her side, the antecubital fossa is prepared with chlorhexidine and draped using maximum barrier precautions (mask, cap and sterile gown, gloves and large drape covering the patient). A tourniquet is placed proximally by an assistant, and a portable ultrasound device is used to identify the basilic or its main branches. A vein can be distinguished from an artery by visualizing compressibility, color flow, and Doppler flow (Fig. 6.1). After a time-out and administration of local anesthesia subcutaneously, venipuncture is performed with the thin-wall entry needle a few centimeters proximal to the antecubital crease to avoid catheter breakage and embolism. When free backflow of venous blood is confirmed, the tourniquet is released and the guidewire carefully threaded into the vein for a distance of 15 to 20 cm. Leaving the guidewire in place, the thin-wall needle is withdrawn and the puncture site enlarged with a scalpel blade. The sheath introducer assembly is threaded over the guidewire with a twisting motion, and the guidewire removed. Next, leaving the sheath in place, the dilator is removed, and the introducer is now ready for PICC insertion. The length of insertion is estimated by measuring the distance along the predicted vein path from the venipuncture site to the manubriosternal junction, using the measuring tape provided in the kit. The PICC is typically supplied with an inner obturator that provides stiffness for insertion. The catheter is trimmed to the desired length and flushed with saline, and the obturator is inserted into the line upto the tip. The PICC/obturator assembly is inserted through the introducer to the appropriate distance, the introducer peeled away, and the obturator removed. The PICC is secured in place, and a chest X-ray is obtained to determine tip position.
If resistance to advancing the PICC is met, options are limited. Techniques such as abducting the arm are of limited value. If a catheter-through- or over-needle device has been used, the catheter must never be withdrawn without simultaneously retracting the needle to avoid catheter shearing and embolism. If the catheter cannot be advanced easily, another site should be chosen.

**Success Rate and Complications**

Using the abovementioned technique, PICC catheters have a 75% to 95% successful placement rate. Overall, PICCs appear to be at least as safe as CVCs, but important complications include sterile phlebitis, thrombosis (especially of the SCV and IJV), infection, limb edema, and pericardial tamponade. Phlebitis may be more common with antecubital CVCs, probably because of less blood flow in these veins as well as the proximity of the venipuncture site to the skin [39]. The risk of pericardial tamponade may also be increased if the catheter tip is inserted too far because of greater catheter tip migration occurring with arm movements [25]. Complications are minimized by strict adherence to recommended techniques for catheter placement and care.

**Internal Jugular Approach**

The IJV has been used for venous access in pediatric and adult patients
for many years, and ultrasound has had its greatest impact by improving the efficiency of IJV cannulation because real-time direct visualization of the vein is easily obtained. This minimizes the impact of hypovolemia or anatomic variations on overall success and has rendered ICU external jugular vein (EJV) catheterization extremely rare. Furthermore, under ultrasound guidance, the central approach is almost always used. Those interested in the anterior or posterior approaches, please refer to prior editions of this textbook. In general, these techniques differ mainly in the point of skin puncture (Fig. 6.2).

FIGURE 6.2 Surface anatomy and various approaches to cannulation of the internal jugular vein. A: Surface anatomy. B: Anterior approach. C: Central approach. D: Posterior approach. The external jugular vein is also shown.

Anatomy

The IJV emerges from the base of the skull through the jugular foramen and enters the carotid sheath dorsally with the internal carotid artery (ICA). It then courses posterolaterally to the artery and runs beneath the sternocleidomastoid (SCM) muscle. The vein lies medial to the anterior portion of the SCM muscle superiorly and then runs beneath the triangle formed by the two heads of the muscle in its medial portion before
entering the SCV near the medial border of the anterior scalene muscle at the sternal border of the clavicle. The junction of the right IJV (which averages 2 to 3 cm in diameter) with the right SCV forming the innominate vein follows a straight path to the SVC. As a result, catheter malposition and looping of the catheter inserted through the right IJV are unusual. In contrast, a catheter passed through the left IJV must negotiate a sharp turn at the left jugulosubclavian junction, which results in a greater percentage of catheter malpositions [40]. This sharp turn may also produce tension and torque at the catheter tip, which can result in a higher incidence of vessel erosion.

A knowledge of the structures neighboring the IJV is essential because they may be compromised by a misdirected needle. The ICA runs medial to the IJV but, rarely, may lie directly posterior or, rarely, anterior. Behind the ICA, just outside the sheath, lie the stellate ganglion and the cervical sympathetic trunk. The dome of the pleura, which is higher on the left, lies caudal to the junction of the IJV and SCV. Posteriorly, at the root of the neck, course the phrenic and vagus nerves. The thoracic duct lies posterior to the left IJV and enters the superior margin of the SCV near the jugulosubclavian junction. The right lymphatic duct has the same anatomic relationship but is much smaller, and chylosus effusions typically occur only with left-sided IJV cannulations.

**Technique of Cannulation**

The *New England Journal of Medicine* has a step-by-step video showing the process of placing an internal jugular CVC [http://www.nejm.org/doi/full/10.1056/NEJMvcm0810156] [41]. With careful preparation of equipment and attention to patient comfort and safety as described earlier, the patient is placed in a 15-degree Trendelenburg position to distend the vein and minimize the risk of air embolism (Fig. 6.2). The use of ultrasonography to guide IJV catheter insertion is reviewed in Video 6.1. Using ultrasonography and a 7.5- to 10-MHz probe, the operator examines both sides of the neck to examine for an appropriate insertion site and factors that would contraindicate access. The IJV is examined in the transverse scanning plane along its length, and reexamined with compression in order to rule out isoechoic thrombus that would contraindicate venous access. It is recommended the operator holds the probe so that the probe marker is always oriented toward the left side of the operator. When the operator is standing at the patient’s head and looking in caudal direction at the patient, the left side of the patient will project to the left side of the screen, given that the screen indicator is to the left on the screen. In this way, movement of the needle tip to the left or right will be seen as corresponding leftward and rightward movements on the screen.
While ipsilateral IJV thrombus is a strong contraindication to venous catheter insertion, the presence of a contralateral thrombus is a relative contraindication to ipsilateral IJV venous access out of concern for the possibility of formation of bilateral IJV thrombosis. Marked respiratory variation of IJV size may occur in the dyspneic patient that may contraindicate insertion attempt. Anatomic variation such as vessel size or position can also be identified with the preprocedure examination.

Before the procedure, the operator examines the anterior chest of the patient in order to rule out pneumothorax. The vascular probe is applied to the anterior chest bilaterally to observe for lung sliding (see Chapter 11 on Lung Ultrasonography). Its presence indicates that there is no pneumothorax before the start of the procedure.

Once an insertion site is identified, the ultrasound machine is positioned such that the operator can visualize the screen with minimal head movement; the line of sight along the needle insertion trajectory is as close as possible to that needed to see the screen. Bedside equipment may need to be moved in order to allow for proper machine positioning. For IJV access, the machine is best positioned contralateral to the planned insertion side with the screen angle adjusted for maximal clarity. The neck is then prepared with chlorhexidine and fully draped, using maximum barrier precautions, including a sterile probe cover with coupling gel. Before the procedure is begun, a time-out is performed. The operator holds the probe in the nondominant hand while examining the lower anterior neck in a transverse scanning plane. The IJV and adjacent carotid artery (CA) are identified, and the position and angle of the probe are adjusted such that the IJV is lateral to the CA, assuming normal anatomy (Fig. 6.3). If the CA is posterior to the IJV, needle insertion at this point into the IJV has high risk of unintentional CA puncture. The CA is usually medial to the IJV, but normal anatomic variants include a medial or posterior position that can only be identified with ultrasonography. Head rotation greater than 40 degrees increases the risk of overlap between the IJV and CA [42]. The most common site for insertion with ultrasonography guidance is toward the apex of the triangle formed by the sternal and clavicular heads of the SCM muscle (Fig. 6.2).
FIGURE 6.3 Ultrasound appearance of the right internal jugular vein and normal relationship with the internal carotid artery.

With the probe held over the target area, the target vessel is centered under the midpoint of the probe. Lidocaine is infiltrated with ultrasonography visualization to assure that the needle tract is well anesthetized. The access needle is held with the dominant hand and inserted through the skin at a 45-degree angle at a point corresponding to the center of the probe. The skin entry site is several millimeters from the probe face. As soon as the needle is through the skin, the scanning plane is angled toward the skin insertion site until the needle tip is identified as a hyperechoic structure that moves predictably with movement of the operator’s hand. The operator moves the needle forward toward the IJV while angling the scanning plane in order to visualize the advance of the needle tip into the vessel. Blood return into the syringe confirms IV placement of the needle.

Some operators prefer to guide the needle using a longitudinal scanning plane while visualizing the needle in its long axis as it approaches and penetrates the IJV. This requires a high level of skill at
needle control because the entire needle must be visualized during the insertion. There is no definitive evidence that supports the transverse or longitudinal approach to needle insertion. One problem with the longitudinal approach is that the CA and IJV are parallel to one another. The inexperienced operator may mistake one vessel for the other with risk of unintentional CA puncture. In our experience, the transverse scanning approach is favored by most operators.

Once venipuncture has occurred, the syringe is removed after ensuring that the backflow of blood is not pulsatile, and the hub is then occluded with a finger to prevent air embolism or excessive bleeding. The angle of the needle should be flattened to ensure smooth passage of the guidewire. The guidewire, with the J-tip oriented appropriately, is then inserted and should pass freely up to 20 cm, at which point the thin-wall needle or catheter is withdrawn. The tendency to insert the guidewire deeper than 15 to 20 cm should be avoided because it is the most common cause of ventricular arrhythmias during insertion and also poses a risk for cardiac perforation. Furthermore, if the patient has an inferior vena cava (IVC) filter in place, the guidewire can become entangled in the filter. Occasionally, the guidewire does not pass easily beyond the tip of the thin-wall needle. The guidewire should then be withdrawn, the syringe attached, and free backflow of blood reestablished and maintained, while the syringe and needle are brought to a more parallel plane with the vein. The guidewire should then pass easily. If resistance is still encountered, rotation of the guidewire during insertion often allows passage. If the wire still does not pass, the proceduralist should consider reaccessing the vessel in a different location. If there is concern that there are anatomic or mechanical obstructions (e.g., distal thrombus) preventing the wire from advancing, an alternative site for catheterization should be considered. Excessive force or manipulation leads only to complications.

The guidewire position is checked with ultrasonography before dilation of the insertion tract. This requires definitive identification of the wire in a long-axis view of the IJV. Unintentional passage of the wire into the CA, even when the needle insertion has been performed with ultrasonography guidance, is always a possibility, so checking wire position before dilation increases the safety of the procedure.

Next, a scalpel is used to make a stab incision at the skin entry site to facilitate passage of the vessel dilator. The dilator is inserted over the wire through the subcutaneous tissues and into the vein, ensuring that control and sterility of the guidewire is not compromised. The dilator is then withdrawn, and pressure is used at the puncture site to control bleeding.
and prevent VAE down the needle tract. Control of the guidewire with one hand while advancing guidewire with the other during dilation will help to minimize kinking of the wire. The catheter is then inserted over the guidewire, ensuring that the operator has control of the guidewire, either proximal or distal to the catheter, at all times to avoid intravascular loss of the wire. The catheter is then advanced 15 to 17 cm (17 to 19 cm for left IJV) into the vein, the guidewire withdrawn, and the distal lumen capped. Then, the proximal and middle lumens of a triple-lumen catheter are flushed with saline and capped. The catheter is sutured securely to limit tip migration and covered with a chlorhexidine-impregnated dressing.

At the end of the procedure, the operator checks for lung sliding in order to rule out pneumothorax. Loss of lung sliding when it was present before the procedure is strong evidence that there is a procedure-related pneumothorax. A chest radiograph should also be obtained to document tip location.

Ultrasonography may be used to confirm CVC position, as an alternative to chest radiography. Following insertion of the CVC, the operator uses the cardiac transducer to visualize the right atrium using the right ventricular inflow, subcostal long-axis, or a modified long-axis IVC view. Using a three-way stopcock and two 10 mL syringes, 10 mL of agitated saline contrast is injected into the distal port of the CVC while the operator is visualizing the right atrium.

The following four patterns result after the injection of the agitated contrast:

1. No contrast enters the atrium. This indicates malposition of the catheter, including the possibility of arterial cannulation.
2. Delayed (<2 seconds) contrast entry into the atrium. This indicates that the catheter is above the level of the SVC.
3. Immediate (>2 seconds) contrast entry into the atrium with laminar flow pattern of contrast into the atrium from the SVC. This indicates appropriate catheter position in the SVC.
4. Immediate contrast opacification of the atrium without laminar flow pattern. This indicates catheter position within the right atrium. This is often confirmed by visualization of the catheter tip in the right atrium.

If there is delayed contrast entry into the atrium, the operator may then examine the IJV and SCV veins to look for aberrant position of the catheter tip in the IJV or the SCV.

The use of agitated saline injection to confirm catheter tip position has been compared with chest radiography with excellent concordance of
results. Vezzani et al. described the injection of agitated saline into the CVC in order to confirm appropriate position of the line tip [43]. They observed that appropriate catheter tip position was associated with a laminar inflow pattern of agitated saline contrast into the right atrium from the SVC that occurred within 2 seconds of the injection, whereas right atrial placement was identified by direct visualization of the catheter tip in the right atrium or by immediate opacification of the right atrium instead of a laminar flow pattern characteristic of SVC placement. No contrast entry into the right atrium or delayed entry of contrast indicated malposition of the catheter. Weekes et al. confirmed these results in two additional studies [44,45]. Both investigators also included examination for postprocedure pneumothorax using ultrasonography.

A major limitation of using ultrasonography is that not all patients have adequate cardiac views to permit visualization of the right atrium. In this case, chest radiography is required. Ultrasonography is useful if the results are unequivocal (i.e., if the catheter tip is visualized in the right atrium, if there is immediate nonlaminar opacification of the right atrium, or if there is immediate laminar flow of agitated saline contrast into the right atrium). With any other result, chest radiography is required. Other problems with using ultrasonography to check for the position of the central venous line tip include that the operator must have skill at cardiac ultrasonography and that it adds time to the procedure. Its advantage is that the skilled operator can promptly determine catheter tip position after insertion. Chest radiography has the advantage of simplicity, but the disadvantage of delay.

Success Rates and Complications

The use of direct ultrasound guidance clearly improves the success rate, decreases the number of attempts and complications, avoids unnecessary procedures by identifying unsuitable anatomy, and minimally impacts insertion time compared to the older anatomic techniques.

The overall incidence of complications in IJV catheterization with ultrasound guidance is quite rare; important complications include ICA puncture, pneumothorax, vessel erosion, thrombosis, and infection. In 2006, Karakitsos et al. randomized 900 patients to ultrasound-guided IJV placement versus the use of a landmark technique [46]. Complications with the ultrasound guidance were significantly lower and occurred very rarely with carotid puncture occurring in 1.1% of patients and hematoma in 0.4%. Hemothorax and pneumothorax did not occur in any of the ultrasound-guided IJV lines. In addition, the time and number of attempts was significantly reduced. This technique is an easily learned skill with proper teaching [46]. In the absence of a bleeding diathesis, arterial punctures are usually benign and are managed conservatively by
applying local pressure for 10 minutes. Even in the absence of clotting abnormalities, a sizable hematoma may form, preventing further catheterization attempts [47]. Unrecognized arterial puncture can lead to catheterization of the ICA with a large-bore catheter or introducer. Options include pulling the catheter and applying pressure, percutaneous closure devices, internal stent grafting, or surgical repair [48,49]. For unintentional ICA catheters, it is safest to obtain vascular surgery consultation, although often removal of the catheter and holding pressure are the initial treatment of choice.

Pneumothorax, which may be complicated by hemothorax, infusion of IV fluid, or tension, is considered an unusual adverse consequence of IJV cannulation and is extraordinarily rare when the procedure is performed under direct ultrasound guidance [46]. Case reports indicate that any complication from IJV catheterization is possible, although in reality, the IJV route is reliable, with a low incidence of major complications. Operator experience is not as important a factor as in SCV catheterization; the incidence of catheter tip malposition is low, and patient acceptance is high. It is best suited for acute, short-term hemodialysis and for elective or urgent catheterizations, especially pulmonary artery catheterizations and insertion of temporary transvenous pacemakers. It is not the preferred site during airway emergencies, for parenteral nutrition, or for long-term catheterization.

External Jugular Vein Approach

With the advent of real-time ultrasound guidance, the EJV is now rarely used for CVC, but it remains an alternative. A description of the anatomy, the technique, and complications can be found elsewhere [50].

Femoral Vein Approach

The common femoral vein (CFV) has many practical advantages for CVC; it is directly compressible, it is remote from the airway and pleura, the technique is relatively simple, and the Trendelenburg position is not required during insertion. However, owing to increased risks for catheter-related infection compared to other sites, CFV catheters should be avoided wherever possible [10–12].

Anatomy

The FV (Fig. 6.4A) is a direct continuation of the popliteal vein and
becomes the external iliac vein at the inguinal ligament. At the inguinal ligament, the CFV lies within the femoral sheath a few centimeters from the skin surface. The CFV lies medial to the femoral artery, which in turn lies medial to the femoral branch of the genitofemoral nerve. The medial compartment contains lymphatic channels and Cloquet node. The external iliac vein courses cephalad from the inguinal ligament along the anterior surface of the iliopsoas muscle to join its counterpart from the other leg and form the IVC anterior to and to the right of the fifth lumbar vertebra. Using ultrasound, the FV can be readily identified by placing the probe a few centimeters caudal to the inguinal ligament, just medial to the arterial pulsation (Fig. 6.4B).

**Technique**

FV cannulation is the easiest of all central venous procedures to learn and perform. The side chosen is based on the operator convenience. Ultrasound confirms the anatomy, identifies the depth needed for venipuncture, rules out preexisting thrombosis, and can directly guide venipuncture. The use of ultrasonography to guide CFV catheter insertion is reviewed in Video 6.2. The patient is placed in the supine position (if tolerated) with the leg extended and slightly abducted at the hip. Excessive hair should be clipped with scissors and the skin prepped with chlorhexidine. The CFV lies 1 to 1.5 cm medial to the arterial pulsation, and the overlying skin is infiltrated with 1% lidocaine.

The machine is positioned across the bed from the operator, and the screen is set at the appropriate angle. The right-handed operator is best positioned on the right side of the patient in order to be able to use their
dominant hand for needle insertion while holding the probe with the left. The opposite applies to the left-handed operator.

Before sterile field preparation, the target area is scanned in its transverse axis to identify any contraindication to central venous access, such as thrombus. The CFV, which is the target vessel, is found medial to the common femoral artery; aberrant anatomy is very uncommon, unlike with the IJV.

Following application of maximum barrier precautions, the CFV is visualized in its transverse axis, and the needle is inserted at a 45-degree angle with constant ultrasonography visualization using the same technique as with IJV access. Needle penetration into the CFV should occur at the level of the inguinal crease. Slightly below this point, the CFV transitions to become the superficial FV that typically lies posterior to the superficial femoral artery. This position strongly contradicts any attempt at venous catheter insertion, out of concern for injury to the overlying artery.

When venous blood return is established, the syringe angle is depressed slightly and free aspiration of blood reconfirmed. The syringe is removed, ensuring that blood return is not pulsatile. The guidewire should pass easily and never forced, although rotation and minor manipulation are sometimes required. The needle is then withdrawn, and the wire is visualized with ultrasonography to be in the CFV before dilation and catheter insertion. Beyond direct visualization of the catheter in the vein, injection of agitated saline with rapid opacification of the right atrium using cardiac ultrasonography confirms an IV position of the catheter. The guidewire insertion site is enlarged with a scalpel and the vein dilator inserted over the wire. The dilator is then withdrawn and a catheter appropriate to clinical requirements inserted, taking care never to lose control of the guidewire. The guidewire is removed, the catheter is secured with a suture, and a chlorhexidine dressing is applied.

Success Rate and Complications

FV catheterization is successful in greater than 90% of patients, including those in shock or cardiopulmonary arrest, and has improved with the use of direct ultrasound guidance [51]. Unsuccessful catheterizations are usually a result of venipuncture failure, hematoma formation, or inability to advance the guidewire into the vein. Operator inexperience may increase the number of attempts and complication rate but does not appear to significantly decrease the overall success rate.

Three complications occur regularly with FV catheterization: arterial
puncture with or without local bleeding, infection, and thromboembolic events. Other reported complications are rare and include scrotal hemorrhage, right lower quadrant bowel perforation, retroperitoneal hemorrhage, puncture of the kidney, and perforation of IVC tributaries. These complications occur when skin puncture sites are cephalad to the inguinal ligament or when long catheters are threaded into the FV.

Femoral artery puncture occurs in 5% to 10% of adults. Most arterial punctures are uncomplicated, but major hematomas may form in 1% of patients, especially in the presence of anticoagulants, fibrinolytics, or antithrombotic agents. As is the case with other routes, ultrasound significantly reduces the rate of these complications [52]. Even in the presence of coagulopathy, arterial puncture with the 18-gauge thin-wall needle is usually of minor consequence, but there is a potential for life-threatening thigh or retroperitoneal hemorrhage [53]. Arteriovenous fistula and pseudoaneurysm are rare chronic complications of arterial puncture; the former is more likely to occur when both femoral vessels on the same side are cannulated concurrently [54].

Infectious and thrombotic complications with FV catheters are more frequent than with other catheters. Specifically, there is a fourfold increased rate of colonization, and threefold increased risk of CRI [10,12]. As such, the Centers for Disease Control and Prevention guidelines recommend avoidance of the femoral site unless absolutely necessary [11].

Although catheter-associated thrombosis is a risk of all CVCs, regardless of the site of insertion, the risks associated with the femoral site are higher. Compared to the subclavian site, the FV was associated with a 14-fold increased odds ratio for thrombotic complications compared to a subclavian CVC [18]. In addition, lower extremity deep vein thromboses have a higher rate of symptomatic embolization compared to those in the upper extremity [35]. Although there are clearly increased risks associated with the FV approach, this site may be required in difficult clinical circumstances. In summary, available evidence supports the view that the FV may be cannulated safely in critically ill adults. FV catheterizations may be performed during airway emergencies and cardiopulmonary arrest, in patients with coagulopathy, in patients who are unable to lie flat, and for access during renal replacement therapy. The most common major complication during FV catheterization is arterial puncture, although this is minimized by direct ultrasound guidance. As stated earlier, infection is more common particularly when compared to the IJV and SCV and, as such, should be avoided if possible.

Subclavian Vein Approach
This route has been used for central venous access for many years and is associated with the most controversy, largely because of the relatively high incidence of pneumothorax and occasional-associated mortality. With the added safety of ultrasound-guided IJV catheterization, there has been some debate about abandonment of landmark-guided SCV catheterization. Ultrasound guidance is possible with the SCV, but it is more technically demanding and may require a different site for venipuncture [11]. The use of ultrasonography to guide SCV catheter insertion is reviewed in Video 6.3. Given these factors, we still believe the SCV is a valuable alternative in certain situations for experienced operators, who should have a pneumothorax rate well under 1%. Inexperienced operators have a far greater rate of pneumothorax; therefore, in settings where relatively inexperienced physicians perform the majority of CVC, the SCV should be used more selectively with close supervision. The advantages of this route include consistent identifiable landmarks, easier long-term catheter maintenance with a comparably lower rate of infection, and relatively high patient comfort. Assuming an experienced operator is available, the SCV is the preferred site for CVC in patients requiring long-term total parenteral nutrition and in patients with elevated intracranial pressure who require hemodynamic monitoring. It should not be considered the primary choice in the presence of thrombocytopenia (platelets < 50,000), for acute hemodialysis, or in patients with high PEEP (i.e., >12 cm H₂O).

**Anatomy**

The SCV is a direct continuation of the axillary vein, beginning at the lateral border of the first rib, extending 3 to 4 cm along the undersurface of the clavicle, and becoming the brachiocephalic vein where it joins the ipsilateral IJV at Pirogoff confluence behind the sternoclavicular articulation (Fig. 6.5). The vein is 1 to 2 cm in diameter, contains a single set of valves just distal to the EJV junction, and is fixed in position directly beneath the clavicle by its fibrous attachments. These attachments prevent collapse of the vein, even with severe volume depletion. Anterior to the vein throughout its course lie the subclavius muscle, clavicle, costoclavicular ligament, pectoralis muscles, and epidermis. Posteriorly, the SCV is separated from the subclavian artery and brachial plexus by the anterior scalenus muscle, which is 10 to 15 mm thick in the adult. Posterior to the medial portion of the SCV are the phrenic nerve and internal mammary artery as they pass into the thorax. Superiorly, the relationships are the skin, platysma, and superficial aponeurosis. Inferiorly, the vein rests on the first rib, Sibson fascia, the cupola of the pleura (0.5 cm behind the vein), and pulmonary apex [50]. The left thoracic duct and right lymphatic duct cross the anterior scalene
muscle to join the superior aspect of the SV near its union with the IJV.

**FIGURE 6.5** Anatomy of the subclavian vein and adjacent structures.

The clavicle presents a significant barrier for ultrasound visualization of the SCV, which may mandate using a different approach [11]. Typically, we identify the axillary vein–SCV junction by placing the probe inferior to the clavicle in the deltopectoral groove. We usually initially produce an axial view of the vein by placing the probe in the cranial–caudal direction. The probe is then rotated 90 degrees to produce a longitudinal view of the vein, which is maintained during venipuncture and guidewire insertion (Fig. 6.6). Although this method is often successful, it may be very difficult in patients with obesity, and tends to be more time consuming.

**FIGURE 6.6** Ultrasound view of the subclavian vein. A: Axial view; B: longitudinal view. See text for details.
Landmark Technique

Although there are many variations, the SCV may be cannulated using surface landmarks by two basic techniques: infraclavicular [55] approach and supraclavicular approach (Fig. 6.7). The differences in success rate, catheter tip malposition, and complications between the two approaches are negligible, although catheter tip malposition and pneumothorax may be less likely with supraclavicular cannulation [56]. In general, when discussing the success rate and incidence of complications of SV catheterization, there is no need to specify the approach used.

![Image](A: Patient positioning for subclavian cannulation. B: Cannulation technique for supraclavicular approach.)

The 18-gauge thin-wall needle is preferable for SCV cannulation. The patient is placed in a 15- to 30-degree Trendelenburg position. Placement of a shoulder roll between the scapulas has been shown to reduce the cross-sectional area of the SCV with ultrasonography imaging. The head is turned slightly to the contralateral side, and the arms are kept to the side. The pertinent landmarks are the clavicle, the two muscle bellies of the SCM, the suprasternal notch, the deltopectoral groove, and the manubriosternal junction. For the infraclavicular approach (Fig. 6.7), the operator is positioned next to the patient’s shoulder on the side to be cannulated. For reasons cited earlier, the left SCV should be chosen for pulmonary artery catheterization; otherwise, the success rate appears to be equivalent regardless of the side chosen. Skin puncture is 2 to 3 cm caudal to the clavicle at the deltopectoral groove, corresponding to the
area where the clavicle turns from the shoulder to the manubrium. Skin puncture should be distant enough from the clavicle to avoid a downward angle of the needle in clearing the inferior surface of the clavicle, which also obviates any need to bend the needle. The path of the needle is toward the suprasternal notch. Using maximum barrier precautions, the skin is prepped with chlorhexidine. After skin infiltration and liberal injection of the clavicular periosteum with 1% lidocaine and a time-out, the 18-gauge thin-wall needle is mounted on a 10-mL syringe. Skin puncture is accomplished with the needle bevel up, and the needle is advanced in the plane until the tip abuts the clavicle. The needle is then “walked” down the clavicle until the inferior edge is cleared. To avoid pneumothorax, it is imperative the needle stay parallel to the floor and not angle down toward the chest. This is accomplished by using the operator’s left thumb to provide downward displacement in the vertical plane after each attempt, until the needle advances under the clavicle.

As the needle is advanced further, the inferior surface of the clavicle should be felt hugging the needle. This ensures that the needle tip is as superior as possible to the pleura. The needle is advanced toward the suprasternal notch during breath holding or expiration, and venipuncture occurs when the needle tip lies beneath the medial end of the clavicle. This may require insertion of the needle to its hub. Blood return may not occur until slow withdrawal of the needle. If venipuncture is not accomplished on the initial attempt, the next attempt should be directed slightly more cephalad. If venipuncture does not occur by the third or fourth attempt, another site should be chosen or another operator should try, because additional attempts are unlikely to be successful and may result in complications.

When blood return is established, the bevel of the needle is rotated 90 degrees toward the heart. The needle is anchored firmly with the left hand, whereas the syringe is detached with the right. Blood return should not be pulsatile, and VAE prophylaxis is necessary at all times. The guidewire is then advanced through the needle to 15 cm and then the needle is withdrawn. To increase the success rate of proper placement of the catheter, the J-wire tip should point inferiorly [57]. The remainder of the procedure is as previously described. Triple-lumen catheters should be sutured at 15 to 16 cm on the right and 17 to 18 cm on the left to avoid intracardiac tip placement [27,58].

For the supraclavicular approach (Fig. 6.7), the important landmarks are the clavicular insertion of the SCM muscle and the sternoclavicular joint. The operator is positioned at the head of the patient on the side to be cannulated. The site of skin puncture is the claviculosternocleidomastoid angle, just above the clavicle and lateral to the insertion of the clavicular head of the SCM. The needle is advanced toward or just caudal to the contralateral nipple just under the clavicle.
This corresponds to a 45-degree angle to the sagittal plane, bisecting a line between the sternoclavicular joint and clavicular insertion of the SCM. The depth of insertion is from just beneath the SCM clavicular head at a 10- to 15-degree angle below the coronal plane. The needle should enter the jugulosubclavian venous bulb after 1 to 4 cm, and the operator may then proceed with catheterization.

**Ultrasound Technique**

The patient is prepared as previously described. The ultrasound machine is positioned so that the operator can visualize the screen with minimal head movement, and the line of sight along the needle insertion trajectory is as close as possible to that required to see the screen. For SCV access, the machine is best positioned contralateral to the planned insertion directly across the patient with the screen angle adjusted for maximal clarity. The operator checks for lung sliding before the procedure to rule out pneumothorax.

Before sterile preparation, the target site is scanned to check for contraindications to IV access, such as thrombus, small size, or excessive respiratory variation. If using the subclavicular approach, the transducer is held in longitudinal orientation and placed on the clavicle using a sagittal scanning plane directed through the medial third of the clavicle. The transducer is then moved laterally on the clavicle until the SCV appears from underneath the clavicle. With further lateral movement of the probe, the target vessel and its paired artery are visualized in the subpectoral area away from the clavicle. The probe is then rotated 90 degrees in order to obtain a long-axis view of the vessel. If using the supraclavicular approach, the transducer is used to examine the supraclavicular area while angling medially. Once the SCV is identified, the transducer is rotated to obtain a view of the structure in longitudinal axis.

Because the SCV may not be as easily compressible as the IJV or FV, it may be difficult to distinguish the SCV from its paired artery. Respiratory variation or the presence of a venous valve is helpful in identifying the SCV. The use of spectral Doppler flow measurements is not recommended unless the operator has expert-level knowledge of Doppler ultrasonography. The use of color Doppler may be useful, because
augmentation of color Doppler signal in the SCV occurs if the ipsilateral upper arm is manually compressed by the operator. Distinguishing the artery from the vein is a key element of performing safe SCV cannulation because the two structures are in close proximity.

Following the application of maximum barrier precautions, the vessel is visualized in its longitudinal axis, and the needle inserted with direct visualization of the entire needle throughout its insertion trajectory. Upon blood return into the syringe, the syringe is removed, and the wire is inserted. The operator holds the probe with their nondominant hand, whereas the needle and syringe are guided by the dominant hand. Some operators prefer to perform needle insertion using ultrasonography guidance with the vessel visualized in its transverse axis (longitudinal scanning plane). In this case, the needle tip is tracked real time, while it is moved forward into the vessel.

Before the dilation of the wire tract, the wire is confirmed to be in the SCV. It may be more difficult to image the wire in the SCV than with the IJV. Scanning from the supraclavicular approach may be helpful in checking for proper wire position. The remainder of the catheter insertion is as described previously. The operator checks for lung sliding in order to rule out procedure-related pneumothorax.

Although there is literature that supports the utility of ultrasonography for SCV venous access, there is consensus that it is difficult to master the technique. Unlike IJV and FV access, where the transverse axis approach is favored, SCV venous access requires that the operator be skilled at controlling the needle in its longitudinal axis. This requires precise insertion of the needle in the midpoint of the short axis of the probe. This may be challenging when the probe cover blocks clear view of the midpoint. In obese or edematous patients, the probe needs to be pressed into the chest tissue, with further difficulty in selecting the initial needle entry site. Even minimal deviation from the narrow tomographic plane of the probe may result in the operator losing control of the needle tip and mistaking the body of the needle for the tip, resulting in injury to the adjacent pleura or artery. Another challenge is maintaining a constant view of the target vessel in longitudinal axis while simultaneously keeping the entire needle in view while it is moved toward the target vessel. For the inexperienced operator, we recommend repeated deliberate practice on a vascular access model before the first closely supervised attempt on a patient. Subclavian venous access with landmark technique uses the clavicle as a definitive guide to successful cannulation, whereas ultrasonography does not. This requires the operator to rely totally on the ultrasonography image for guidance, and to discount the clavicle as a relevant landmark. When using ultrasonography for needle guidance into the SCV, the needle entry site is often more lateral and at a steeper angle than with the landmark technique. Initially, this may be disconcerting to
the operator who is used to using landmark technique.

**Success and Complication Rates**

SCV catheterization is successful in 90% to 95% of cases, generally on the first attempt [59]. Unsuccessful catheterizations are a result of venipuncture failure or inability to advance the guidewire or catheter. Catheter tip malposition occurs in 5% to 20% of cases and tends to be more frequent with the infraclavicular approach. Malposition occurs most commonly to the ipsilateral IJV and contralateral SCV and is usually correctable without repeat venipuncture.

The overall incidence of noninfectious complications varies depending on the operator experience and the circumstances under which the catheter is inserted. Large series involving several thousand SCV catheters have reported an incidence of major complications of 1% to 3% [60]. Factors resulting in a higher complication rate are operator inexperience, multiple attempts at venipuncture, emergency conditions, variance from standardized technique, and body mass index. Major noninfectious complications include pneumothorax, arterial puncture, and thromboembolism. There are many case reports of isolated major complications involving neck structures or the brachial plexus; the reader is referred elsewhere for a complete listing of reported complications [60].

Pneumothorax accounts for one-fourth to one-half of reported complications, with an incidence of about 1.5%. The incidence varies inversely with the operator experience [60]. There is no magic figure whereby an operator matures from inexperienced to experienced. Fifty catheterizations are cited frequently as a cutoff number, but it is reasonable to expect an operator to be satisfactorily experienced after having performed fewer. For the experienced operator, a pneumothorax incidence of less than 1% is expected [61]. Most pneumothoraces are a result of lung puncture at the time of the procedure, but late-appearing pneumothoraces have been reported.

Approach to the treatment of pneumothoraces depends on the size of the defect. Many will require thoracostomy tube drainage with a small chest tube and a Heimlich valve, but some can be managed conservatively with 100% oxygen and serial radiographs or needle aspiration only [62]. Rarely, a pneumothorax is complicated by tension, hemothorax, infusion of IV fluid (immediately or days to weeks after catheter placement), chyle, or massive subcutaneous emphysema. Bilateral pneumothoraces can occur from unilateral attempts at venipuncture. Pneumothorax can result in death, especially when it goes unrecognized [63].

Subclavian artery puncture occurs in 0.5% to 1.0% of cases, constituting one-fourth to one-third of all complications. Arterial
puncture is usually managed easily by applying pressure above and below the clavicle. Bleeding can be catastrophic in patients with coagulopathy, especially thrombocytopenia. As with other routes, arterial puncture may result in arteriovenous fistula or pseudoaneurysm [12,60].

Clinical evidence of central venous thrombosis, including SVC syndrome, development of collaterals around the shoulder girdle, and pulmonary embolism, is very rare occurring in 0% to 3% of SCV catheterizations, but routine phlebography performed at catheter removal reveals a much higher incidence of thrombotic phenomena. The importance of the discrepancy between clinical symptoms and radiologic findings is unknown, but upper extremity thrombosis, even if asymptomatic, is not a totally benign condition [61]. Duration of catheterization, catheter material, and patient condition probably impact the frequency of thrombosis, but to an uncertain degree.

In summary, the SCV is an extremely reliable and useful route for CVC, but because of the relatively high rate of pneumothorax and the increased success rate of ultrasound-guided IJV catheterization, its use should be limited to those operators skilled in the technique. Inexperienced operators should use an alternative site except with close supervision. Experienced operators should continue to use this route for certain indications (Table 6.1), but should scrupulously avoid it in patients who cannot tolerate a pneumothorax (severe lung disease, one lung), or in patients with severe coagulopathy, especially platelets <50,000.

Wilkins, 2012.

Arterial catheterization remains an extremely important skill for the critical care physician. Arterial catheters are frequently required for close blood pressure monitoring of the hemodynamically unstable patient and for repeated arterial blood gas sampling for patients with respiratory failure or acid–base disorders. Newer technologies that necessitate arterial access continue to mature. In this sense, arterial pulse contour analysis can be used to predict fluid responsiveness and compute cardiac output (CO) reliably and less invasively for appropriately selected patients [1]. Although advancements of noninvasive technology, such as transcutaneous PCO$_2$ monitoring and pulse oximetry, may decrease the need for arterial catheter placement, intensivists need to be proficient with the insertion and interpretation of arterial catheter systems. In this chapter, we review the principles of hemodynamic monitoring and discuss the indications, insertion techniques, management, and complications of arterial cannulation.

INDICATIONS FOR ARTERIAL CANNULATION

Arterial catheters should be inserted only when they are specifically required and removed immediately when no longer needed. Too often they are left in place for convenience to allow easy access to blood sampling, which leads to increased laboratory testing and excessive diagnostic blood loss (DBL) [2,3], as well as an increased risk of infection.
It should be noted that there are no large prospective clinical trials addressing the question of whether arterial cannulation influences mortality of intensive care unit (ICU) patients. The indications for arterial cannulation can be grouped into three broad categories (Table 7.1): (1) hemodynamic monitoring (blood pressure and/or CO/pulse contour analysis); (2) frequent arterial blood gas sampling; (3) diagnostic or therapeutic interventions, including intra-aortic balloon pump (IABP) use and arterial administration of drugs, and procedures such as vascular stenting or embolization.

Noninvasive, indirect blood pressure measurements determined by auscultation of Korotkoff sounds distal to an occluding cuff (Riva–Rocci method) are generally accurate, although systolic readings are consistently lower compared to a simultaneous direct measurement. Although noninvasive blood pressure measurements are satisfactory for a majority of ICU patients, in very critically ill patients indirect techniques may provide grossly inaccurate blood pressure readings. Automated noninvasive oscillometric blood pressure measurement devices can also be inaccurate, providing discrepant readings of ≥10 mm Hg when compared to direct arterial measurements of critically ill patients [4,5]. The proprietary algorithms of these devices are in part to blame, and
although their adjustment can result in higher accuracy, they still render imprecise measurements for an unacceptably high number of patients [6]. Based on these findings, and the fact that each automated device has a different proprietary algorithm that may not be validated for all ICU patients, the routine use of oscillometric devices cannot be recommended for all highest acuity critically ill patients, and for patients with severe hemodynamic instability.

Arterial catheterization allows monitoring of beat-to-beat changes and prompt initiation of appropriate therapeutic modalities; variations in individual pressure waveforms can also be diagnostic. Waveform inspection can rapidly diagnose electrocardiogram lead disconnection, indicate the presence of aortic valvular disease, help determine the effect of dysrhythmias on perfusion, and reveal the impact of the respiratory cycle on blood pressure (pulsus paradoxus). In addition, for mechanically ventilated patients, responsiveness to fluid boluses may be predicted by calculating the systolic pressure variation (SPV) or pulse pressure variation (PPV) from the arterial waveform, and stroke volume variation from the pulse contour analysis. For patients on mechanical ventilation, all of these techniques have been shown to predict, with a high degree of accuracy, the likelihood of responding (with an increase in stroke volume) to a fluid volume challenge [1]. It should be noted that all of these patients were well sedated, on a mechanical ventilation mode different from pressure support and receiving a tidal volume between 8 and 10 mL per kg of ideal body weight [1]. Lower tidal volumes, patient movement, and dysrhythmias could affect the accuracy of this diagnostic intervention.

CO can be monitored continuously using calibrated arterial pulse contour analysis. This method relies on the assumption that the contour of the arterial pressure waveform is proportional to the stroke volume [7,8]. This, however, does not take into consideration the differing impedances among the arteries of individuals under different disease states and, therefore, requires calibration with another method of CO determination [8]. This is usually done with the indicator dilution or transpulmonary thermodilution technique [8]. Uncalibrated pulse contour analysis devices, which do not use an additional method of determining CO, are available. They estimate impedance based upon a proprietary formula that uses waveform and patient demographic data [8,9]. This method has significant limitations (i.e., atrial fibrillation) and can provide inaccurate CO estimations for many critically ill patients [8,9].
Management of complicated patients in critical care units typically requires multiple laboratory and arterial blood gas determinations. In these situations, arterial cannulation facilitates obtaining laboratory tests without repeated needle sticks and vessel trauma. In our opinion, an arterial catheter for blood gas determination is justified when a patient requires two or more measurements daily.
EQUIPMENT, MONITORING, TECHNIQUES, AND SOURCES OF ERROR

The equipment necessary to display and measure an arterial waveform includes (a) an appropriate intra-arterial catheter, (b) fluid-filled tubing with stopcocks (ideally, it should be short and noncompliant), (c) a transducer, (d) a constant flush device with a fluid bag pressurized to 300 mm Hg, and (e) electronic monitoring equipment (signal processor, amplifier, and display). Using this equipment, intra-arterial pressure changes are transmitted through the hydraulic (fluid-filled) elements to the transducer, which converts mechanical displacement into a proportional electrical signal. This signal is amplified, processed, and displayed as a waveform by the monitor. Undistorted presentation of the arterial waveform depends on the performance of each component and an understanding of potential problems that can interfere with the overall fidelity of the system.

The major problems inherent to pressure monitoring with a catheter system are inadequate dynamic response, improper zeroing and leveling, zero drift, and improper transducer/monitor calibration. Most physicians are aware of zeroing and leveling techniques but do not appreciate the importance of dynamic response for ensuring system fidelity. Catheter-tubing-transducer systems used for pressure monitoring can best be characterized as underdamped second-order dynamic systems with mechanical parameters of elasticity, mass, and friction. Overall, the dynamic response of such a system is determined by its natural frequency and damping coefficient.

Every system has a frequency at which it oscillates freely: the natural frequency. When an external force of similar frequency to the natural frequency is applied to a system, it will begin to oscillate at its maximum amplitude, a phenomenon called resonance. If the arterial pressure waveform approaches the natural frequency of the blood pressure measuring system, it will resonate causing progressive amplification of the output signal, and erroneously elevated blood pressure readings, particularly systolic, will result. To ensure a flat frequency response (accurate recording across a spectrum of frequencies), the natural frequency of a monitoring system should be at least five times higher than the highest frequency in the input signal. The natural frequency of a system may be increased by reducing its length, reducing its compliance, reducing its density, and increasing its diameter.

Physiologic peripheral arterial waveforms have a fundamental frequency of 3 to 5 Hz and therefore, the natural frequency of a system...
used to monitor arterial pressure should ideally be greater than 20 Hz to avoid resonance and systolic overshoot. The system component most likely to cause amplification of a pressure waveform is the hydraulic element. A good hydraulic system will have a natural frequency between 10 and 20 Hz, which may overlap with arterial pressure frequencies. Thus, amplification can occur, which may require damping to accurately reproduce the waveform [12].

The damping coefficient is a measure of how quickly an oscillating system dissipates energy and comes to rest. A system with a high damping coefficient dissipates mechanical energy well, causing a diminution in the transmitted waveform. Conversely, a system with a low damping coefficient results in underdamping and overestimation of systolic pressures. The damping coefficient of a system is increased by increasing its viscosity, increasing its density, decreasing its diameter, increasing its length, or decreasing its elasticity. Damping coefficient and natural frequency together determine the dynamic response of a recording system. If the natural frequency of a system is less than 7.5 Hz, the pressure waveform will be distorted no matter what the damping coefficient is. On the other hand, a natural frequency of 24 Hz allows a range in the damping coefficient of 0.15 to 1.1, without resultant distortion of the pressure waveform [10].

Although there are other techniques [13], the easiest method to test the damping coefficient and natural frequency of a monitoring system is the fast-flush test (also known as the square wave test). This is performed at the bedside by briefly opening and closing the continuous flush device, which exposes the system to a flush of fluid, with a pressure of 300 mm Hg producing a square wave displacement on the monitor followed by a few smaller oscillations and a return to baseline (Fig. 7.1). An optimal fast-flush test results in one undershoot followed by a small overshoot and then settles to the patient’s waveform. The natural frequency is determined by dividing the paper or display speed by the interval between two successive oscillations. The damping coefficient can be calculated by measuring two successive peak amplitudes and determining their ratio. This ratio is then converted to the damping coefficient by equation or by matching it to published graphs and charts [10].
For peripheral pulse pressure monitoring, an adequate fast-flush test usually corresponds to a natural frequency of 10 to 20 Hz coupled with a damping coefficient of 0.5 to 0.7. To ensure the continuing fidelity of a monitoring system, dynamic response validation by fast-flush test should be performed frequently: at least every 8 hours, with every significant change in patient hemodynamic status, after each opening of the system (zeroing, blood sampling, tubing change), and whenever the waveform appears damped [10].

With consideration of the above concepts, the critical reader would note that many of the factors that increase the damping coefficient can decrease the natural frequency, and vice versa, producing effects that might be considered paradoxical. The interaction between damping coefficient and natural frequency is indeed complex and an exhaustive review of their physical characteristics is beyond the scope of this chapter. A more detailed discussion regarding hemodynamic waveforms can be found elsewhere [14]. However, we should emphasize that most components of the commercial monitoring systems are designed to optimize the frequency response of the entire system and that most clinically relevant effects of damping on the pressure waveform can be explained by the following examples.

Overdamped tracings (Fig. 7.1A) are usually caused by problems that are correctable, such as large air bubbles, tube or catheter kinks, clot formation, loose connections, a deflated pressure bag, or anatomic factors affecting the catheter (vasoconstriction). Catheter kinks can be fixed quickly by straightening the tubing, and thrombus occlusion can be rectified by flushing, usually. Air bubbles in the tubing and connecting stopcocks can be cleared by flushing through a stopcock. Loose connections and deflated pressure bags can be reconnected or replaced.

Underdamped tracings are common and have been seen in approximately 30% of selected patients admitted to the ICU [15]. An underdamped tracing results in resonance and systolic overshoot (Fig 7.1B) and is commonly secondary to excessive tubing length. Standard, noncompliant tubing is provided with most disposable transducer kits and should be as short as possible to minimize signal amplification [11]. The 18- and 20-gauge catheters used to gain arterial access were not considered to be a major source of distortion in the past, but a recent study showed that underdamping/resonance is associated with radial
artery catheters with larger length and diameter (10 cm and 0.8 mm, respectively) and that the placement of a 20-gauge cannula (8 cm length and 0.6 mm diameter) decreases this phenomenon [15]. Other factors associated with underdamping are the presence of polydistrectual arteriopathy, chronic obstructive pulmonary disease, and arterial hypertension [15]. Increased sedation decreases underdamping [15].

Currently available disposable transducers incorporate microchip technology, are very reliable, and have relatively high resonant frequencies [16]. The transducer is attached to the electronic monitoring equipment by a cable. Modern monitors have internal calibration, filter artifacts, and print the display on request. The digital readout display is usually an average of values over time and therefore does not accurately represent beat-to-beat variability. Monitors provide the capability to freeze a display with on-screen calibration to measure beat-to-beat differences in amplitude precisely. This allows measurement of the effect of ectopic beats on blood pressure, PPV, SPV, or assessment of the presence and severity of pulsus paradoxus.

For the transducer to work accurately, atmospheric pressure and hydrostatic pressure (pressure exerted by the blood column) should be corrected for by zeroing and leveling the system. Improper zeroing and leveling, because of either a change in patient position or zero drift, is the single most important source of error. Zeroing can be performed by opening the transducer stopcock to room air, thus exposing it to atmospheric pressure. Leveling is done by aligning the transducer with the patient’s heart, at the fourth or fifth intercostal space, in the midaxillary line, hence decreasing the effects of hydrostatic pressure on the system. Under these conditions, the pressure reading is calibrated to zero by the monitor. Zeroing and leveling should be repeated with every change of patient position (a transducer that is below the zero reference line will result in falsely high readings and vice versa), when significant changes of blood pressure occur, and routinely every 6 to 8 hours because of zero drift. Disposable pressure transducers incorporate semiconductor technology and are very small, yet rugged and reliable, and because of standardization, calibration of the system is not necessary [16].

Transducers are faulty on occasion, however, and calibration may be checked by attaching a mercury manometer to the stopcock and applying 100, 150, and/or 200 mm Hg pressure. A variation of ±5 mm Hg is acceptable. If calibration is questioned and the variation is out of range, or a manometer is not available for testing, the transducer should be replaced. When zero referencing and calibration are correct, a fast-flush test will assess the system’s dynamic response.

Many monitors can be adjusted to filter out frequencies above a certain limit, which can eliminate frequencies in the input signal causing resonance. However, this may also cause inaccurate readings if clinically
important frequencies are excluded. Ideally, an exhaustive search for potential causes of resonance and their solutions should be attempted before deciding to filter these frequencies.
TECHNIQUE OF ARTERIAL CANNULATION

Site Selection

Several factors are important when selecting the site for arterial cannulation. The ideal artery has extensive collateral circulation that will maintain the viability of distal tissues if thrombosis occurs. The site should be comfortable for the patient, accessible for insertion and nursing care, and close to the monitoring equipment. Sites involved by infection, disruption of the epidermal barrier, thrombosis, or ischemia need to be avoided. Certain procedures, such as coronary artery bypass grafting, may dictate preference for one site over another. Physicians should also be cognizant of differences of pulse contour recorded at different sites. Because the pressure pulse wave travels outward from the aorta, it encounters arteries of decreased caliber and elasticity, with multiple branch points, causing reflections of the pressure wave. This results in a peripheral pulse contour with increased slope and amplitude, causing artificially elevated pressure readings. As a result, distal extremity artery recordings yield higher systolic values than central aortic or femoral artery recordings. Diastolic pressures tend to be less affected, and mean arterial pressures (MAPs) measured at the alternative sites are similar [17]. Therefore, MAP has been accepted as a more precise target, than systolic or diastolic pressures, for the titration of intravenous fluid and vasoconstrictor therapy in shock.

The most commonly used sites for arterial cannulation of adults are the radial, femoral, axillary, dorsalis pedis, and brachial arteries. Additional sites include the ulnar and superficial temporal arteries. Peripheral arteries are cannulated percutaneously with a 5-cm, 20-gauge, nontapered polytetrafluoroethylene (PTFE, Teflon) catheter-over-needle, whereas larger arteries are cannulated using the Seldinger technique with a prepackaged kit, typically containing a 15-cm, 18-gauge PTFE catheter, appropriate introducer needles, and guidewire.

Arterial catheterization is performed by physicians from many different specialties and usually the procedure to be performed dictates the site chosen. For example, insertion of an IABP is almost always performed through the femoral artery regardless of the specialty of the physician performing the procedure. Critical care physicians need to be facile with arterial cannulation at all sites, but the radial artery is used successfully
for most arterial catheterizations performed for critically ill adults. Each site has unique complications, and they should be taken into account by the proceduralist [18–20]. Radial artery cannulation is usually attempted initially unless the patient is in severe shock, on high-dose vasopressors, and/or pulses are not palpable or adequately visualized with the use of the portable ultrasound. Traditional practice recommended femoral artery cannulation when the former failed, but it has been noted that femoral catheters may be associated with more frequent bloodstream infections [21]. Therefore, cannulation of alternative sites such as the dorsalis pedis, brachial, and axillary arteries should be considered first; however, data on the relative risk of infection of these sites are lacking [21]. Which of these is chosen depends on the exact clinical situation and the expertise of the operator.

Radial Artery Cannulation

A thorough understanding of normal arterial anatomy and common anatomic variants greatly facilitates insertion of catheters and management of unexpected findings at all sites. The radial artery is one of two final branches of the brachial artery. It courses over the flexor digitorum sublimis, flexor pollicis longus, and pronator quadratus muscles and lies just lateral to the flexor carpi radialis in the forearm. As the artery enters the floor of the palm, it ends in the deep volar arterial arch at the level of the metacarpal bones and communicates with the ulnar artery. A second site of collateral flow for the radial artery occurs via the dorsal arch running in the dorsum of the hand (Fig. 7.3).

The ulnar artery runs between the flexor carpi ulnaris and flexor digitorum sublimis in the forearm, with a short course over the ulnar nerve. In the hand, the artery runs over the transverse carpal ligament and becomes the superficial volar arch, which forms an anastomosis with a small branch of the radial artery. These three anastomoses provide excellent collateral flow to the hand [22]. A competent superficial or deep palmar arch must be present to ensure adequate collateral flow. At least one of these anastomoses may be absent in up to 20% of individuals.

Evaluation of Collateral Circulation of the Hand

Hand ischemia is a rare but potential devastating complication of radial artery catheterization that may require amputation [23]. Hand ischemia is rare because of the rich collateral circulation described earlier that ensures perfusion even if one of the main arteries thrombose. Historically, the modified Allen test [24] was used prior to radial catheterization to detect patients in whom the collateral circulation may not be intact and presumably at increased risk for hand ischemia. However, as a screening tool, the Allen test does not have a very good
predictive value [25], and our institution, as well as many others, has abandoned its routine use. Doppler ultrasound has been used to screen selected patients for harvesting of the radial artery in elective coronary artery bypass grafting case series, and no ischemic complications were seen [26]. It is unclear if the patients that were excluded from these studies were indeed at increased risk of hand ischemia or not; ethical concerns may prevent the formulation of a clinical trial to answer that question. Based upon this study, we use Doppler ultrasound to evaluate collateral hand circulation with the caveat that it has not yet been validated for critically ill adults.

The best way to prevent hand ischemia is to avoid radial catheterization of patients perceived to be at increased risk (i.e., high-dose vasopressor therapy, scleroderma, vasculopathy) and to perform and document clinical evaluation of hand perfusion at frequent intervals. Any change of the hand distal to a radial artery catheter that suggests decreased perfusion (color or temperature change, paresthesias, or loss of capillary refill) should prompt immediate removal of the catheter and further investigation if the changes do not reverse.

Percutaneous Insertion

The hand is positioned in 30 to 60 degrees of dorsiflexion with the aid of a roll of gauze and armband, avoiding hyperabduction of the thumb. We next use ultrasound to determine the locations, depth, and size of the artery. The volar aspect of the wrist is prepared (alcoholic chlorhexidine) and draped using sterile technique, and approximately 0.5 mL of lidocaine is infiltrated on both sides of the artery through a 25-gauge or smaller needle. Lidocaine serves to decrease patient discomfort and may decrease the likelihood of arterial vasospasm [27]. The catheter over the needle approach necessitates cap, mask, sterile gloves, and a small fenestrated drape, whereas the Seldinger technique requires maximum barrier precautions. A time out confirming correct patient, correct site, correct equipment, and informed consent is necessary before the procedure begins.

A 20-gauge, nontapered, PTFE 5-cm catheter-over-needle apparatus is used for puncture. Entry is made at a 30- to 60-degree angle to the skin approximately 3 to 5 cm proximal to the distal wrist crease. An ultrasound image of the radial artery at this position is shown in Figure 7.2A. The needle and cannula are advanced until blood return is apparent in the hub, signifying intra-arterial placement of the tip of the needle. A small amount of additional advancement is necessary for the cannula tip to fully enter the artery lumen. With this accomplished, needle and cannula are brought flat to the skin and the cannula is advanced to its hub with a firm, steady rotary action. Correct positioning is confirmed by
pulsatile blood return after removal of the needle. If the initial attempt is unsuccessful, subsequent attempts should be more proximal, rather than closer to the wrist crease, because the artery is of greater diameter [22], although this may increase the incidence of catheters becoming kinked or occluded [28].

If difficulty is encountered when attempting to pass the catheter, carefully replacing the needle and slightly advancing the whole apparatus may remedy the problem. Alternatively, a fixation technique can be attempted (Fig. 7.3). Advancing the needle and catheter through the far wall of the vessel purposely transfixes the artery. The cannula is then pulled back with the needle partially retracted within the catheter until vigorous arterial blood return is noted. The catheter can then be advanced up the arterial lumen, using the needle as a reinforcing stent.
Anatomy of the radial artery. Note the collateral circulation to the ulnar artery through the deep volar arterial arch and dorsal arch.

Catheters with self-contained guidewires to facilitate passage of the cannula into the artery are available (Fig. 7.4). Percutaneous puncture is made in the same manner, but when blood return is noted in the catheter
The guidewire is passed through the needle into the artery, serving as a stent for subsequent catheter advancement. The guidewire and needle are then removed and placement confirmed by pulsatile blood return. The cannula is then secured firmly, attached to transducer tubing, and the site covered with a dressing. Video instruction for the insertion of a radial arterial catheter is available in Video 7.1 and on the Internet [29].

**FIGURE 7.4** Cannulation of the radial artery. A: A towel is placed behind the wrist, and the hand is immobilized with tape. B: The catheter-needle-guidewire apparatus is inserted into the skin at a 30- to 60-degree angle. C: The guidewire is advanced into the artery after pulsatile blood flow is obtained. D: The catheter is advanced over the guidewire into the artery.

**Dorsalis Pedis Artery Cannulation**

Dorsalis pedis artery catheterization is uncommon in most critical care units; compared with the radial artery, the anatomy is less predictable and the success rate is lower [30]. The dorsalis pedis artery is the main blood supply of the dorsum of the foot. The artery runs from the ankle to the great toe. It lies very superficial and just lateral to the tendon of the extensor hallucis longus. The dorsalis pedis anastomoses with branches
from the posterior tibial (lateral plantar artery) and, to a lesser extent, peroneal arteries, creating an arterial arch network analogous to the one in the hand. The use of a catheter with a self-contained guidewire is recommended for dorsalis pedis catheterization. The foot is placed in plantar flexion and prepared in the usual fashion. Vessel entry is achieved approximately halfway up the dorsum of the foot where the palpable pulse is strongest; advancement is the same as with cannulation of the radial artery. Use of the ultrasound may increase the rate of successful insertion. Patients usually find catheterization here more painful but less physically limiting. Systolic pressure readings are usually 5 to 20 mm Hg higher with dorsalis pedis catheters than with radial artery catheters, but MAP values are generally similar.

Brachial Artery Cannulation

The brachial artery is cannulated in the bicipital groove proximal to the antecubital fossa at a point where there is no collateral circulation (Fig. 7.2B). In theory, clinical ischemia should be a greater risk, but in most series brachial artery catheters have complication rates comparable to other routes [20,22,31,32]. Even when diminution of distal pulses occurs, because of either proximal obstruction or distal embolization, clinical ischemia is unlikely. An important anatomic consideration is that the median nerve lies in close proximity to the brachial artery and may be punctured in 1% to 2% of cases [32]. This usually causes only transient paresthesias, but median nerve palsy has been reported. Median nerve palsy is a particular risk for patients with coagulopathy because even minor bleeding into the fascial planes can produce compression of the median nerve [33]. Coagulopathy may be considered a relative contraindication to brachial artery cannulation. Given all these considerations, brachial artery cannulation should be considered when the radial and dorsalis pedis sites are not available or appropriate. Ultrasound guidance for all brachial artery catheterizations is strongly recommended.

Cannulation of the brachial artery is best performed using a prepackaged kit designed for larger arteries. The brachial artery is punctured by extending the arm at the elbow and locating the pulsating vessel by palpation and ultrasound, a few centimeters proximal to the antecubital fossa, just medial to the bicipital tendon. Once catheterization is established, the elbow must be kept in full extension to avoid kinking
or breaking the catheter. Clinical examination of the hand, and Doppler studies when indicated, should be performed and documented frequently while the brachial catheter is in place. The catheter should be promptly removed if diminution of any pulse occurs or there is evidence of embolism. An additional concern is air embolism because placement of a 15-cm catheter puts its tip in the axillary artery.

Femoral Artery Cannulation

Indwelling femoral artery catheters may be associated with a higher risk of health care–acquired infection [21] and should be placed only when insertion at other sites is not appropriate. The femoral artery is large and often palpable when other sites are not, easy to visualize with ultrasound and the technique of cannulation is simple to learn. The most common reason for failure to cannulate is severe atherosclerosis or stenosis from prior vascular procedures involving both femoral arteries. Complications unique to this site are rare but include retroperitoneal hemorrhage and intra-abdominal viscus perforation. These complications occur because of poor technique (puncture above the inguinal ligament) or in the presence of anatomic variations (i.e., large inguinal hernia). Ischemic complications from femoral artery catheters are very rare.

The external iliac artery becomes the common femoral artery at the inguinal ligament (Fig. 7.5). The artery courses under the inguinal ligament near the junction of the medial and the middle third of a straight line drawn between the pubis and the anterior superior iliac spine (Fig. 7.2C). The artery is cannulated using the Seldinger technique and any one of several available prepackaged kits. Kits contain the equivalent of a 19-gauge thin-wall needle, appropriate guidewire, and a 15-cm, 18-gauge PTFE catheter. The patient lies supine with the leg extended and slightly abducted. Skin puncture should be 3 to 5 cm caudal to the inguinal ligament to minimize the risk of retroperitoneal hematoma or bowel perforation, which can occur when needle puncture of the vessel is cephalad to the inguinal ligament. The thin-wall needle is directed, bevel up, cephalad at a 45-degree angle. When arterial blood return is confirmed, the needle and syringe may need to be brought down against the skin to facilitate guidewire passage. The guidewire should advance smoothly, but minor manipulation and rotation is sometimes required when the wire meets resistance at the needle tip or after it has advanced into the vessel. Inability to pass the guidewire may be because of an intimal flap over the needle bevel or atherosclerotic plaques in the vessel. In the latter instance, cannulation of that femoral artery may prove impossible. When the guidewire will not pass beyond the needle tip, it should be withdrawn and blood return reestablished by advancing the needle or repeat vascular puncture. The guidewire is then inserted,
the needle withdrawn and the catheter threaded over the guidewire to its hub. The guidewire is withdrawn, the catheter sutured securely and connected to the transducer tubing.

**FIGURE 7.5** Anatomy of the femoral artery and adjacent structures. The artery is cannulated below the inguinal ligament.

**Axillary Artery Cannulation**

Axillary artery catheterization of critically ill adults occurs infrequently, but centers experiencing it report low rates of complications [18,20,34]. The axillary artery is large and frequently palpable when all other sites are not and has a rich collateral circulation. The tip of a 15-cm catheter inserted through an axillary approach lies in the subclavian artery, and
thus central arterial pressures are effectively measured. The central location of the tip makes cerebral air embolism a greater risk; therefore, left axillary catheters are preferred for the initial attempt because air bubbles passing into the right subclavian artery are more likely to traverse the aortic arch. Caution should be exercised when flushing axillary catheters, which is best accomplished manually using low pressures and small volumes.

The axillary artery begins at the lateral border of the first rib as a continuation of the subclavian artery and ends at the inferior margin of the teres major muscle, where it becomes the brachial artery. The optimal site for catheterization is the junction of the middle and lower third of the vessel, which usually corresponds to its highest palpable point in the axilla. At this point, the artery is superficial and is located at the inferior border of the pectoralis major muscle (Fig. 7.2D). The artery is enclosed in a neurovascular bundle, the axillary sheath, with the medial, posterior, and lateral cords of the brachial plexus. Medial to the medial cord is the axillary vein. Not surprisingly, brachial plexus neuropathies have been reported from axillary artery cannulation [35]. Coagulopathy is a relative contraindication, because the axillary sheath can rapidly fill with blood from an uncontrolled arterial puncture, resulting in a compressive neuropathy.

The axillary artery is cannulated using the Seldinger technique and a prepackaged kit. The arm is abducted, externally rotated, and flexed at the elbow by having the patient place the hand under his or her head. The artery is palpated at the lower border of the pectoralis major muscle and fixed against the shaft of the humerus. After site preparation and local infiltration with lidocaine, the thin-wall needle is introduced at a 30- to 45-degree angle to the vertical plane until return of arterial blood. The remainder of the catheterization proceeds as described for femoral artery cannulation.

An additional insertion technique, which is guided by ultrasound imaging, has been reported [36]. With this method, the arm is abducted to a 90-degree angle, the second portion of the axillary artery is identified by longitudinal sonographic views, the needle is then advanced under real-time imaging through the pectoral muscles and clavipectoral fascia until pulsatile blood return is seen. The artery is subsequently catheterized using the Seldinger technique. The potential benefits of this technique may include the ability to visualize and avoid puncturing the structures surrounding the axillary artery (i.e., brachial plexus) and an anterior insertion site that allows for easier care of the catheter.
Utility of Ultrasonography for Arterial Catheterization

Ultrasonography has useful application related to arterial catheterization. Although ultrasound guidance to decrease complication rates of central venous catheter insertion has become relatively commonplace, fewer clinicians are familiar with the use of ultrasound to guide arterial catheterization \[37\]. Traditional arterial palpation techniques for catheterization can be especially challenging for patients with obesity, edema, small vessel caliber, and shock states that obscure pulsatility. Additionally, repeated attempts after initial failure often result in arterial spasm, leading to further failed attempts with increased risk of complications. Multiple studies and meta-analyses have proven the benefits of real-time ultrasound-guided arterial catheterization by demonstrating increased success rates and overall reductions of rates of complications \[38,39\]. International, evidence-based recommendations advocate that ultrasound guidance as the method of choice for any kind of vascular cannulation, given its higher safety and efficacy \[40\]. The use of ultrasonography to guide radial artery catheter insertion is presented in Video 7.1.

Two-dimensional ultrasound and a high-frequency linear array transducer (5 to 10 MHz) are used for catheterization. Before sterile draping, potential access sites should be scanned for vessel depth, caliber, patency, tortuosity, atheromatous plaques, and adjacent vein and nerve location. Arteries are recognized and differentiated from veins and nerves by a discrete round shape, relatively thick walls, and above all pulsatility—which can be accentuated by partial compression of the artery. Color and pulsed-wave Doppler techniques can be used for vessel identification but are not required.

Sterile barrier precautions and a sterile probe cover should be used. The operator’s dominant hand is used for needle control, whereas the nondominant hand is used to hold the transducer. The artery is centered on the screen. Both the transverse and the longitudinal views can be utilized as long as the operator maintains needle tip visualization throughout the procedure. Although the transverse approach allows for easier visualization and catheterization of smaller and tortuous arteries, the longitudinal approach may reduce perforation of the posterior arterial wall by direct visualization of the entire needle throughout the procedure \[41\]. A local anesthetic is injected under ultrasound guidance by visualizing an enlarging hypoechoic area in the subcutaneous tissue.

When using a transverse approach, the introducer needle is inserted
through the skin at a 45-degree angle slightly distal to the transducer. Superficial arteries may require a shallower angle of insertion. Before any further advancement, the needle tip must be visualized under the skin surface, within the soft tissue, as a hyperechoic dot. The transducer is slowly angled back and forth to distinguish the needle tip from the shaft. Only when the tip is identified should the operator continue to slowly advance the needle toward the target artery. This can be achieved by advancing the needle and transducer simultaneously or by angulating the probe while advancing the needle. Both techniques require the needle tip to remain in view at all times. Once the artery is penetrated and blood flow obtained, the ultrasound probe is placed on the sterile field and catheterization is completed using the modified Seldinger technique. The wire should be visualized and confirmed within the artery before deploying the catheter. When the longitudinal approach is utilized, the needle must be advanced in-plane with the transducer at all times because any out-of-plane movement can potentially damage nonvisualized adjacent structures [41].

In addition to guidance, ultrasound can be used to identify the potential for complications. Before puncture of the radial artery, a Doppler ultrasound-guided Allen test can be performed to detect appropriate arterial blood flow to the hand [42]. The location of femoral artery puncture is directly related to postprocedural complications. “Low Stick” punctures below the bifurcation of the common femoral artery are associated with hematoma, pseudoaneurysm, arteriovenous fistula, and ischemic limb complications. Recognition and avoidance of the external iliac artery, superficial, and deep femoral arteries significantly reduces vascular complications. Retroperitoneal hemorrhage can be reduced by avoiding “high sticks” at or above the inferior epigastric artery. To reduce embolic complications, care should be taken to avoid catheterization through atheromas. Postprocedural complications, like hematomas, arteriovenous fistulas, and pseudoaneurysms, can be readily identified with ultrasound [43].
COMPLICATIONS OF ARTERIAL CANNULATION

Arterial cannulation is a relatively safe invasive procedure. Although estimates of the total complication rates range from 15% to 40%, clinically relevant complications occur in 5% or less of cannulations (Table 7.2). Risk factors for infectious and noninfectious complications have been identified and are listed in Table 7.3 [20,44,45].

Thrombosis

Thrombosis is the single most common complication of intra-arterial catheters. The incidence of thrombosis varies with the site, method of detection, size of the cannula, and duration of cannulation. Thrombosis is common with radial and dorsalis pedis catheters, but clinical sequelae are rare because of the collateral circulation [44,45]. When a 20-gauge nontapered PTFE catheter with a continuous 3 mL per hour heparinized-saline flush is used to cannulate the radial artery for 3 to 4 days, thrombosis of the vessel can be detected by Doppler study in 5% to 25% of cases [45]. Use of a flush solution containing heparin is no longer standard at our institution because of concern for heparin-induced thrombocytopenia (HIT); the incidence of thrombosis does not appear to be significantly higher using saline flush [46,47]. The risk of radial thrombosis seems to be proportionally associated with the diameter of the catheter used [20], and smaller catheters may be protective.

Thrombosis often occurs after catheter removal. Women have a preponderance of flow abnormalities following radial artery cannulation, likely explained by smaller arteries and a greater tendency to exhibit

vasospasm [28]. Generally, thrombosed arteries recanalize by 3 weeks after removal of the catheter. Despite the high incidence of Doppler-detected thrombosis, clinical ischemia of the hand is rare and usually resolves following catheter removal. Symptomatic occlusion requiring surgical intervention occurs in fewer than 1% of cases, but can be catastrophic with tissue loss or amputation of the hand [23]. Most patients who develop clinical ischemia have an associated contributory cause, such as prolonged circulatory failure with high-dose vasopressor therapy requirements [44].

Regular inspection of the extremity for unexplained pain or signs of ischemia followed by immediate removal of the catheter, if indicated, minimize significant ischemic complications. When evidence of ischemia persists after catheter removal, anticoagulation, thrombolytic therapy, embolectomy, surgical bypass, or cervical sympathetic blockade are treatment options and should be pursued aggressively [23,44]. Early consultation of a vascular surgeon is recommended in this situation.

Cerebral Embolization

Continuous flush devices used with arterial catheters are designed to deliver 3 mL per hour of fluid from an infusion bag pressurized to 300 mm Hg. It was demonstrated that with rapid flushing of radial artery lines with relatively small volumes of radiolabeled solution, traces of the solution could be detected in the central arterial circulation in a time frame representative of retrograde flow [48]. Moreover, injection of greater than 2 mL of air into the radial artery of small primates results in retrograde passage of air into the vertebral circulation [35]. Factors that increase the risk of retrograde passage of air are patient size and position (air travels up in a sitting patient), injection site, and flush rate. Air embolism has been cited as a risk mainly for radial arterial catheters but logically could occur with all arterial catheters, especially axillary and brachial artery catheters. The risk is minimized by clearing all air from the tubing before flushing, opening the flush valve for no more than 2 to 3 seconds at a time, and avoiding overaggressive manual flushing of the line.

Diagnostic Blood Loss

DBL is blood loss that occurs in the patient because of frequent blood sampling obtained for laboratory testing. The significance of DBL is underappreciated. It is a particular problem for patients with standard arterial catheter setups that are used as the site for sampling, because 3 to 5 mL of blood are typically wasted (to avoid heparin/saline contamination) every time a sample is obtained. For patients with frequent arterial blood gas determinations, DBL can be substantial and
results in a red cell transfusion [49]. There are several ways to minimize DBL, including tubing systems employing a reservoir for blood sampling, continuous intra-arterial blood gas monitoring, point of care microchemistry analysis, and the use of pediatric collection tubes. Given the expense and risks of blood transfusions, every ICU should have a blood conservation policy in place that includes minimizing DBL. Protocols that are designed to optimize laboratory utilization have resulted in significant cost savings and reduced transfusion requirements in our, as well as in other, institutions [50].

Other Mechanical and Technical Complications

Other noninfectious complications reported with arterial catheters are pseudoaneurysm formation, hematoma, local tenderness, hemorrhage, neuropathies, and catheter embolization [20]. Heparin use for flushing of vascular catheters may confer a small risk of HIT [51] and is associated with increased costs. The data supporting the use of heparin to maintain patency of arterial catheters is poor and does not provide sufficient proof for continuation of this practice [52]. Thus, it is our opinion that standard flushing of catheters should be done with saline solutions.

Infections

Infectious sequelae are the most important clinical complications caused by arterial cannulation. See Chapter 81 for a detailed review of catheter-related infections (CRI s). Catheter-associated infection is usually initiated when skin flora invades the intracutaneous tract, causing colonization of the catheter, and when not locally contained, bacteremia. An additional source of infection is contaminated infusate from the pressure monitoring system, which is at greater risk of infection than central venous catheters because (a) the transducer can become colonized as a consequence of stagnant flow, (b) the flush solution is infused at a slow rate (3 mL per hour) and may hang for several days, and (c) the stopcocks in the system can serve as entry sites for bacteria when they are accessed by several different personnel to obtain blood samples.

Appreciation of the mechanisms responsible for initiating arterial CRI is important for understanding how to minimize infection; thorough operator and site preparation is paramount. It should be noted that only one study evaluated the impact of maximum barrier precautions for the placement of radial and dorsalis pedis catheters [53] and that no studies have addressed this matter for larger arteries. With those considerations in mind, it is our practice to use full barrier precautions for all large artery insertions. Chlorhexidine should be used for skin preparation [54] and use of a chlorhexidine soaked dressing at the insertion site is an excellent practice. Breaks of sterile technique during insertion mandate
termination of the procedure and replacement of compromised equipment. Nursing personnel should follow strict guidelines when drawing blood samples or manipulating connections. Blood withdrawn to clear the tubing prior to drawing samples should not be reinjected unless a specially designed system is in use [55]. Inspection of the site at the start of every nursing shift is mandatory, and the catheter should be evaluated and removed promptly when indicated. Routine change of the pressure monitoring system does not reduce infectious complications and may represent another opportunity to introduce colonization.

Arterial cannulation remains an underrecognized source of bloodstream infections. Historically, it was thought that arterial catheters had a lower risk for infection than central venous catheters, but research has proven this to be no longer true. Impressive reductions in overall CRI have occurred as a result of clinical research, better technology, and an emphasis on patient safety [21,56,57]. Using modern techniques, arterial catheter-related colonization may occur in up to 5% to 10% of catheters, but the incidence of catheter-related bacteremia is in the range of 0.5 to 2.0 per 1,000 catheter-days [18,19,21,56–58].

The site of insertion as an important factor impacting the incidence of infection has been a controversial issue. Previous research studies had conflicting reports about the risk of infection of femoral catheterizations, and the consensus among physicians was that they were generally safe [18–21,30]. A recent meta-analysis looked at this issue and found that CRI occurred in 1.5% of femoral catheterizations in contrast to 0.3% of radial cannulations [21]. The calculated relative risk of infection of the femoral site was 1.94 times greater than the radial site [21]. Rigorous data about the risk of infection of other insertion sites are not available. Based on these findings, placement of a catheter in the femoral artery should be avoided, when feasible, by cannulating another arterial site. In this regard, we have had a change of practice in our institution, where more brachial and axillary cannulations are done now.

Catheter duration is important and likely related to increased risk of infection [57]. We believe 5 to 7 days is an appropriate time to reassess the need for and the location of arterial catheterization [21,57], but each institution should determine its own catheter-associated infection rate so that rational policies can be formulated based on existing local infection rates.

When arterial catheter infection does occur, *Staphylococcus* species are commonly isolated. Gram-negative organisms are less frequent; they are predominantly contaminated infusate or equipment-related infections.
Infection with Candida species is a greater risk for prolonged catheterization of the glucose-intolerant or immunocompromised patient but has been reported for all types of patients. PTFE catheters have a greater resistance to Escherichia coli and Pseudomonas aeruginosa \[20\]. Catheter-associated bacteremia should be treated with a 7- to 14-day course of appropriate antibiotics. For complicated cases, longer courses are sometimes necessary.

The optimal evaluation of febrile catheterized patients can be a challenging problem (see Chapter 79). If the site appears abnormal or the patient has sepsis of no other identified etiology, the catheter should be removed. More specific guidelines are difficult to recommend, and individual factors should always be considered. In general, arterial catheters in place less than 5 days are unlikely to be the source of fever unless insertion was contaminated. Catheters in place 5 days or longer should be changed to a different site, given the safety of arterial cannulation and the possibility of infection. Guidewire exchanges are not recommended in our institution because of the potential risk of infection.
RECOMMENDATIONS

The radial artery is an appropriate initial site for percutaneous arterial cannulation. When the radial artery is not appropriate for cannulation, other sites such as the brachial, axillary, dorsalis pedis, or femoral arteries can be safely cannulated. Most centers have more experience with femoral artery cannulation, but this site has been linked with a higher risk of infection and should be avoided as much as possible. Coagulopathy may be considered a relative contraindication for brachial and axillary arterial cannulation. Ultrasound guidance should be used for all catheterizations anticipated to be difficult and to avoid complications when a coagulopathy is present. Routine ultrasound use is also strongly advocated because it is associated with a higher first pass success rate and, potentially, less insertion time and fewer sites for successful placement. Arterial catheters should be removed as soon as clinically indicated, to decrease the risk of iatrogenic infection. Finally, arterial catheters are associated with overutilization of blood tests and iatrogenic anemia, and their prompt discontinuation may decrease these phenomena.

In the emergency department and critical care environment, management of the airway to ensure optimal ventilation and oxygenation is of prime importance. Although initial efforts should be directed toward improving oxygenation and ventilation without intubating the patient (see Chapter 167), these interventions may fail and the placement of an endotracheal (ET) tube may be required. Although ET intubation is best left to the trained specialist, emergencies often require that the procedure be performed before a specialist arrives. Because intubated patients are commonly seen in the intensive care unit (ICU) and coronary care unit, all physicians who work in these environments should be skilled in the techniques of airway management, ET intubation, and management of intubated patients. For those intensivists who do not have the necessary training to become credentialed by their hospital for airway management, taking structured airway management courses, participating in simulation and intubating patients in the operating room or ICU under the watchful eye of a mentor should lead the way to the awarding of privileges.

ANATOMY

An understanding of the techniques of ET intubation and potential complications is based on knowledge of the anatomy of the respiratory passages [1]. Although a detailed anatomic description is beyond the scope of this book, an understanding of some features and relationships is essential to performing intubation.
Nose
The roof of the nose is partially formed by the cribriform plate. The anatomic proximity of the roof to intracranial structures dictates that special caution be exercised during nasotracheal intubations. This is particularly true in patients with significant maxillofacial injuries.

The mucosa of the nose is provided with a rich blood supply from branches of the ophthalmic and maxillary arteries, which allow air to be warmed and humidified. Because the conchae provide an irregular, highly vascularized surface, they are particularly susceptible to trauma and subsequent hemorrhage. The orifices from the paranasal sinuses and nasolacrimal duct open onto the lateral wall. Blockage of these orifices by prolonged nasotracheal intubation may result in sinusitis.

Mouth and Jaw
The mouth is formed inferiorly by the tongue, alveolar ridge, and mandible. The hard and soft palates compose the superior surface, and the oropharynx forms the posterior surface. Assessment of the anatomic features of the mouth and jaw is essential before orotracheal intubation. A clear understanding of the anatomy is also essential when dealing with a patient who has a difficult airway and when learning how to insert airway devices such as the laryngeal mask airway (LMA; discussed in “Management of the Difficult Airway” section).

Nasopharynx
The base of the skull forms the roof of the nasopharynx, and the soft palate forms the floor. The roof and the posterior walls of the nasopharynx contain lymphoid tissue (adenoids), which may become enlarged and compromise nasal airflow or become injured during nasal intubation, particularly in children. The Eustachian tubes enter the nasopharynx on the lateral walls and may become blocked secondary to swelling during prolonged nasotracheal intubation.

Oropharynx
The soft palate defines the beginning of the oropharynx, which extends inferiorly to the epiglottis. The palatine tonsils protrude from the lateral walls and, in children, occasionally become so enlarged that exposure of the larynx for intubation becomes difficult. A large tongue can also cause oropharyngeal obstruction. Contraction of the genioglossus muscle normally moves the tongue forward to open the oropharyngeal passage during inspiration. Decreased tone of this muscle (e.g., in the
anesthetized state) can cause obstruction. The oropharynx connects the posterior portion of the oral cavity to the hypopharynx.

**Hypopharynx**

The epiglottis defines the superior border of the hypopharynx, and the beginning of the esophagus forms the inferior boundary (approximately 1 cm below the cricoid ring). The larynx is anterior to the hypopharynx. The pyriform sinuses that extend around both sides of the larynx are part of the hypopharynx.

**Larynx**

The larynx ([Fig. 8.1](#)) is bounded by the hypopharynx superiorly and is continuous with the trachea inferiorly. The thyroid, cricoid, epiglottic, cuneiform, corniculate, and arytenoid cartilages compose the laryngeal skeleton. The thyroid and cricoid cartilages are readily palpated in the anterior neck. The cricoid cartilage articulates with the thyroid cartilage and is joined to it by the cricothyroid ligament. When the patient’s head is extended, the cricothyroid ligament can be pierced with a scalpel or large needle to provide an emergency airway (see [Chapter 9](#)). The cricoid cartilage completely encircles the airway. It is attached to the first cartilage ring of the trachea by the cricotracheal ligament. The anterior wall of the larynx is formed by the epiglottic cartilage, to which the arytenoid cartilages are attached. Fine muscles span the arytenoid and thyroid cartilages, as do the vocal cords. The true vocal cords and space between them are collectively termed the *glottis* ([Fig. 8.2](#)). The glottis is the narrowest space in the adult upper airway. In children, the cricoid cartilage defines the narrowest portion of the airway. Because normal phonation relies on the precise apposition of the true vocal cords, even a small lesion can cause hoarseness. Lymphatic drainage to the true vocal cords is sparse. Inflammation or swelling caused by tube irritation or trauma may take considerable time to resolve. The superior and recurrent laryngeal nerve branches of the vagus nerve innervate the structures of the larynx. The superior laryngeal nerve supplies sensory innervation from the inferior surface of the epiglottis to the superior surface of the vocal cords. From its take-off from the vagus nerve, it passes deep to both branches of the carotid artery. A large internal branch pierces the thyrohyoid membrane just inferior to the greater cornu of the hyoid. This branch can be blocked with local anesthetics for oral or nasal intubations in awake patients. The recurrent laryngeal branch of the vagus nerve provides sensory innervation below the cords. It also supplies all the muscles of the larynx except the cricothyroid, which is innervated by the external branch of the superior laryngeal nerve.
**FIGURE 8.1** Anatomy of the larynx, anterior, and lateral aspects.

**FIGURE 8.2** Superior view of the larynx (inspiration).

Trachea
The average adult trachea is 15 cm long. Its external skeleton is composed of a series of C-shaped cartilages. It is bounded posteriorly by the esophagus and anteriorly for the first few cartilage rings by the thyroid gland. The trachea is lined with ciliated cells and has mucus glands; through the beating action of the cilia, foreign substances are propelled toward the larynx. The carina is located at the fourth thoracic vertebral level (of relevance when judging proper ET tube positioning on chest radiograph). The right main bronchus takes off at a less acute angle than the left, making right main bronchial intubation more common if the ET tube is in too far.
EMERGENCY AIRWAY MANAGEMENT

In an emergency situation, establishing adequate ventilation and oxygenation assumes primary importance. Too frequently, inexperienced personnel believe that this requires immediate intubation; however, attempts at intubation may delay establishment of an adequate airway. Such efforts are time consuming, can produce hypoxemia and arrhythmias, and may induce bleeding and regurgitation, making subsequent attempts to intubate significantly more difficult and contributing to significant patient morbidity and even mortality [2,3]. Some simple techniques and principles of emergency airway management can play an important role until the arrival of an individual who is skilled at intubation.

Airway Obstruction

Compromised ventilation often results from upper airway obstruction by the tongue, by substances retained in the mouth, or by laryngospasm. Relaxation of the tongue and jaw leading to a reduction in the space between the base of the tongue and the posterior pharyngeal wall is the most common cause of upper airway obstruction. Obstruction may be partial or complete. The latter is characterized by total lack of air exchange. The former is recognized by inspiratory stridor and retraction of neck and intercostal muscles. If respiration is inadequate, the head-tilt–chin-lift or jaw-thrust maneuver should be performed. In patients with suspected cervical spine injuries, the jaw-thrust maneuver (without the head tilt) may result in the least movement of the cervical spine. To perform the head-tilt maneuver, a palm is placed on the patient’s forehead and applied pressure to extend the head about the atlanto-occipital joint. To perform the chin lift, several fingers of the other hand is placed in the submental area and lifted the mandible. Care must be taken to avoid airway obstruction by pressing too firmly on the soft tissues in the submental area. To perform the jaw thrust, lift up on the angles of the mandible (Fig. 8.3). Both of these maneuvers open the oropharyngeal passage. Laryngospasm can be treated by maintaining positive airway pressure using a face mask and bag valve device (see the following section). If the patient resumes spontaneous breathing, establishing this head position may constitute sufficient treatment. If obstruction persists, a check for foreign bodies, emesis, or secretions should be performed.
In an obtunded or comatose patient, the soft tissues of the oropharynx become relaxed and may obstruct the upper airway. Obstruction can be alleviated by placing the thumbs on the maxilla with the index fingers under the ramus of the mandible and rotating the mandible forward with pressure from the index fingers (arrow). This maneuver brings the soft tissues forward and, therefore, frequently reduces the airway obstruction.

Use of Face Mask and Bag Valve Device

If an adequate airway has been established and the patient is not breathing spontaneously, oxygen can be delivered via face mask and a bag valve device. It is important to establish a tight fit with the face mask, covering the patient’s mouth and nose. To perform this procedure, the mask is applied initially to the bridge of the nose and drawn it downward toward the mouth, using both hands. The operator stands at the patient’s head and presses the mask onto the patient’s face with the left hand. The thumb should be on the nasal portion of the mask, the index finger near the oral portion, and the rest of the fingers spread on the left side of the patient’s mandible so as to pull it slightly forward (Fig. 8.4). The bag is then alternately compressed and released with the right hand. A good airway is indicated by the rise and fall of the chest; moreover, lung–chest wall compliance can be estimated from the amount of pressure required to compress the bag. The minimum effective insufflation pressure should be used to decrease the risk of insufflating the stomach with gas which increases the risk of aspiration.
Airway Adjuncts

If proper positioning of the head and neck or clearance of foreign bodies and secretions fails to establish an adequate airway, several airway adjuncts may be helpful if an individual who is skilled in intubation is not immediately available. An oropharyngeal or a nasopharyngeal airway occasionally helps to establish an adequate airway when proper head positioning alone is insufficient (Figs. 8.5 and 8.6). The oropharyngeal airway is semi-circular and made of plastic or hard rubber. The two types are the Guedel airway, with a hollow tubular design, and the Berman airway, with airway channels along the sides. Both types are most easily inserted by turning the curved portion toward the palate as it enters the mouth. It is then advanced beyond the posterior portion of the tongue and rotated downward into the proper position (Fig. 8.5). Often, depressing the tongue or moving it laterally with a tongue blade helps to position the oropharyngeal airway. Care must be exercised not to push the tongue into the posterior pharynx, causing or exacerbating obstruction. Because insertion of the oropharyngeal airway can cause gagging or vomiting or both, it should be used only in unconscious patients.
The nasopharyngeal airway is a soft tube approximately 15 cm long, which is made of rubber or plastic. It is inserted through the nostril into the posterior pharynx (Fig. 8.6). Before insertion, the airway should be lubricated with an anesthetic gel, and, preferably, a vasoconstrictor should be administered into the nostril. The nasopharyngeal airway should not be used in patients with extensive facial trauma or cerebrospinal rhinorrhea because it could be inserted through the cribriform plate into the brain.
The indications for ET intubation can be divided into four broad categories: (a) acute airway obstruction, (b) excessive pulmonary secretions or inability to clear secretions adequately, (c) loss of protective reflexes, and (d) respiratory failure (Table 8.1).

Preintubation Evaluation

Even in the most urgent situation, a rapid assessment of the patient’s airway anatomy can expedite the choice of the proper route for intubation, the appropriate equipment, and the most useful precautions to be taken. In the less emergent situation, several moments of preintubation evaluation can decrease the likelihood of complications and increase the probability of successful intubation with minimal trauma.

Anatomic structures of the upper airway, head, and neck must be examined, with particular attention to abnormalities that might preclude a particular route of intubation. Evaluation of cervical spine mobility, temporomandibular joint function, and dentition is important. Any abnormalities that might prohibit alignment of the oral, pharyngeal, and laryngeal axes should be noted.

Cervical spine mobility is assessed by flexion and extension of the neck (performed only after ascertaining that no cervical spine injury exists). The normal range of neck flexion–extension varies from 165 to 90 degrees, with the range decreasing approximately 20% by 75 years of age. Conditions associated with decreased range of motion include any cause of degenerative disk disease (e.g., rheumatoid arthritis, osteoarthritis, ankylosing spondylitis), previous trauma, or older than 70 years of age. Temporomandibular joint dysfunction can occur in any form of degenerative arthritis (particularly rheumatoid arthritis), in any condition that causes a receding mandible, and in rare conditions such as acromegaly.

Examination of the oral cavity is mandatory. Loose, missing, or chipped teeth and permanent bridgework are noted, and removable bridgework and dentures should be taken out. Mallampati et al. [4] (Fig. 8.7) developed a clinical indicator based on the size of the posterior aspect of the tongue relative to the size of the oral pharynx. The patient should be sitting, with the head fully extended, protruding the tongue and phonating [5]. When the faucial pillars, the uvula, the soft palate, and the posterior pharyngeal wall are well visualized, the airway is classified as
class I, and a relatively easy intubation can be anticipated. When the uvula and soft palate (class II), soft palate and base of uvula only (class III), or hard palate only (soft palate not seen) are visible, there is an increasing greater chance of problems visualizing the glottis during direct laryngoscopy. Difficulties in orotracheal intubation may also be anticipated if (a) the patient is an adult and cannot open his or her mouth more than 40 mm (two-finger breadths), (b) the distance from the thyroid notch to the mandible is less than three-finger breadths (less than or equal to 7 cm), (c) the patient has a high arched palate, or (d) the normal range of flexion–extension of the neck is decreased (less than or equal to 80 degrees) [6]. The positive predictive values of these tests alone or in combination are not particularly high; however, a straightforward intubation can be anticipated if the test results are negative [7]. In the emergency setting, only about 30% of airways can be assessed in this manner [8]. The MACOCHA (Mallampati, sleep Apnea syndrome, Cervical spine limitation, mouth Opening, Coma, Hypoxia, presence of an Anesthesiologist) score was developed by de Jong et al. (Fig. 8.8). Scores above 4 were associated with a greater than 20% incidence of difficult intubation [9]. Whenever possible, patients in need of elective and emergent airway management should be assessed for indicators of difficult mask ventilation because this may significantly influence the decision on the primary approach to airway management. In a large analysis, five independent predictors of impossible mask ventilation were identified by the authors: neck radiation changes, male sex, a diagnosis of sleep apnea, Mallampati class III or IV airway, and the presence of a beard [10]. Among these factors, neck radiation changes were the most significant predictor of impossible mask ventilation.
FIGURE 8.7 The modified Mallampati classification to predict difficult intubation. Class I: soft palate, uvula, fauces, and pillars are visible; Class II: soft palate and uvula are visible; Class III: soft palate and base of uvula visible; Class IV: only hard palate visible.

FIGURE 8.8 The MACOCHA score. (A) Original cohort and (B) is the validation cohort. An increasing score is associated with a higher degree of difficulty with intubation. Graphs A and B are the original and validation cohorts, respectively.

Education and Intubation Management

Emergent intubation in the acute care setting is associated with a high complication rate. It is, therefore, important to provide adequate training to practitioners working in this environment, and have an adequate number of trained personnel be available to assist the operator. Furthermore, a standardized approach to emergency airway management can improve patient outcomes. Although training on a mannequin is an important first step in acquiring competency in performing ET
Intubation, an investigation including nonanesthesia trainees has shown that approximately 50 supervised ET intubations in the clinical setting are needed to achieve a 90% probability of competent performance [11]. Whenever possible, residents and licensed independent practitioners should be supervised by an attending physician trained in emergency airway management during the procedure. This approach has led to a significant reduction in immediate complications from 21.7% to 6.1% in one pre- and postintervention analysis [12].

In addition, the use of a management bundle consisting of interventions that, in isolation have been shown to decrease complications during emergency airway management, can further improve patient outcomes. Elements that should be included in this approach are preoxygenation with noninvasive positive-pressure ventilation (NIPPV) if feasible, presence of two operators, rapid sequence intubation (RSI) with cricoid pressure, capnography, lung protective ventilation strategies, fluid loading prior to intubation unless contraindicated, and preparation and early administration of sedation and vasopressor use if needed [13].
**EQUIPMENT FOR INTUBATION**

Assembly of all appropriate equipment before attempted intubation can prevent potentially serious delays in the event of an unforeseen complication. Most equipment and supplies are readily available in the ICU but must be gathered so they are immediately at hand. To reduce the risk of having missing equipment during critical times, an intubation bag or cart with all necessary equipments and supplies should be developed. A supply of 100% oxygen and a well-fitting mask with attached bag valve device are mandatory, as is suctioning equipment, including a large-bore tonsil suction attachment (Yankauer) and suction catheters. Adequate lighting facilitates airway visualization. The bed should be at the proper height, with the headboard removed and the wheels locked. Other necessary supplies include gloves, Magill forceps, oral and nasal airways, laryngoscope handle and blades (straight and curved) and/or videolaryngoscope, ET tubes of various sizes, stylet, tongue depressors, a syringe for cuff inflation, and tape for securing the ET tube in position. **Table 8.2** is a checklist of supplies needed.

Laryngoscopes

The two-piece laryngoscope has a handle containing batteries that power the bulb in the blade. The blade snaps securely into the top of the handle, making the electrical connection. Failure of the bulb to illuminate suggests improper blade positioning, bulb failure, a loose bulb, or dead batteries. Modern laryngoscope blades with fiberoptic lights obviate the problem of bulb failure. Many blade shapes and sizes are available. The two most commonly used blades are the curved (MacIntosh) and straight (Miller) blades (Fig. 8.9). Although pediatric blades are available for use with the adult-sized handle, most anesthesiologists prefer a smaller handle for better control in the pediatric population. The choice of blade shape is a matter of personal preference and experience; however, one study has suggested that less force and head extension are required when performing direct laryngoscopy with a straight blade [14]. Video-assisted laryngoscopes (Fig. 8.10) are now widely available in many perioperative and acute care specialties and, in many institutions, have become the predominant method by which laryngoscopy and intubation are performed. The blades are equipped with antifogging technology and, distal angles of approximately 60 degrees to improve the view of the glottis and provide a view from near the tip of the scope. These devices have been shown to improve the success rate for difficult ET intubation performed by experienced physicians [15], as well as the rate of successful intubation by untrained individuals when performing normal intubations [16]. Hagberg has compiled an extensive list of commercially available videolaryngoscopes [17].
blade is curved. The blade tip is placed in the vallecula, and the handle of the laryngoscope pulled forward at a 45-degree angle. This allows visualization of the epiglottis. The Miller blade is straight. The tip is placed posterior to the epiglottis, pinning the epiglottis between the base of the tongue and the straight laryngoscope blade. The motion on the laryngoscope handle is the same as that used with the MacIntosh blade.

FIGURE 8.10 Videolaryngoscope with screen.
Note the 60-degree angle of the blade.

Endotracheal Tubes

The internal diameter of the ET tube is measured using both millimeters and French units. This number is stamped on the tube. Tubes are available in 0.5-mm increments, starting at 2.5 mm. Lengthwise dimensions are also marked on the tube in centimeters, beginning at the distal tracheal end. Selection of the proper tube diameter is of utmost importance and is a frequently underemphasized consideration. The resistance to airflow varies with the fourth power of the radius of the ET tube. Thus, selection of an inappropriately small tube can significantly increase the work of breathing. Moreover, certain diagnostic procedures (e.g., bronchoscopy) done through ET tubes require appropriately large tubes (see Chapter 10). In general, the larger the patient, the larger the ET tube that should be used. Approximate guidelines for tube sizes and lengths by age are summarized in Table 8.3. Most adults should be intubated with an ET tube that has an inner diameter of at least 8.0 mm, although occasionally nasal intubation in a small adult requires a 7.0-mm tube.

### Endotracheal Tube Cuff

ET tubes have low-pressure, high-volume cuffs to reduce the incidence of ischemia-related complications. Tracheal ischemia can occur any time cuff pressure that exceeds capillary pressure (approximately 32 mm Hg), thereby causing inflammation, ulceration, infection, and dissolution of cartilaginous rings. Failure to recognize this progressive degeneration sometimes results in erosion through the tracheal wall (into the innominate artery if the erosion was anterior or the esophagus if the
erosion was posterior) or long-term sequelae of tracheomalacia or tracheal stenosis. With cuff pressures of 15 to 30 mm Hg, the low-pressure, high-volume cuffs conform well to the tracheal wall and provide an adequate seal during positive-pressure ventilation. Although low cuff pressures can cause some damage (primarily ciliary denudation), major complications are rare. Nevertheless, it is important to realize that a low-pressure, high-volume cuff can be converted to a high-pressure cuff if sufficient quantities of air are injected into the cuff.
ANESTHESIA BEFORE INTUBATION

Because patients who require intubation often have a depressed level of consciousness, anesthesia is usually not required. If intubation must be performed on the alert, responsive patient, sedation or general anesthesia exposes the individual to potential pulmonary aspiration of gastric contents because protective reflexes are lost. This risk is a particularly important consideration if the patient has recently eaten and must be weighed against the risk of various hemodynamic derangements that might occur secondary to tracheal intubation and initiation of positive-pressure ventilation. Laryngoscopy in an inadequately anesthetized patient can result in tachycardia and an increase in blood pressure. This may be well tolerated in younger patients but may be detrimental in a patient with coronary artery disease or raised intracranial pressure. Sometimes laryngoscopy and intubation may result in a vasovagal response, leading to bradycardia and hypotension. Initiation of positive-pressure ventilation in a hypovolemic patient can lead to hypotension from diminished venous return.

Some of these responses can be attenuated by providing local anesthesia to the nares, mouth, and/or posterior pharynx before intubation. Topical lidocaine (1% to 4%) with phenylephrine (0.25%) or cocaine (4%, 200 mg total dose) can be used to anesthetize the nasal passages and provide local vasoconstriction. This allows the passage of a larger ET tube with less likelihood of bleeding. Aqueous lidocaine–phenylephrine or cocaine can be administered via atomizer, nose dropper, or long cotton-tipped swabs inserted into the nares. Alternatively, viscous 2% lidocaine can be applied via a 3.5-mm ET tube or small nasopharyngeal airway inserted into the nose. Anesthesia of the tongue and posterior pharynx can be accomplished with lidocaine spray (4% to 10%) administered via an atomizer or an eutectic mixture of two local anesthetics cream applied on a tongue blade and oral airway [18]. Alternatively, the glossopharyngeal nerve can be blocked bilaterally with an injection of a local anesthetic, but this should be performed by experienced personnel.

Anesthetizing the larynx below the vocal cords before intubation is controversial. The cough reflex can be compromised, increasing the risk of aspiration. However, tracheal anesthesia may decrease the incidence of arrhythmias or untoward circulatory responses to intubation and improve patient tolerance of the ET tube. Clinical judgment in this situation is necessary. Several methods can be used to anesthetize these structures. Transtracheal lidocaine (4%, 160 mg) is administered by cricothyroid membrane puncture with a small needle to anesthetize the
trachea and larynx below the vocal cords. However, it may be difficult to identify the cricothyroid membrane by palpation in all patients [19]. Ultrasonography will reliably identify the cricothyroid membrane. Alternatively, after exposure of the vocal cords with the laryngoscope, the cords can be sprayed with lidocaine via an atomizer. Aerosolized lidocaine (4%, 6 mL) provides excellent anesthesia to the mouth, pharynx, larynx, and trachea. The superior laryngeal nerve can be blocked with 2 mL of 1.0% to 1.5% lidocaine injected just inferior to the greater cornu of the hyoid bone. The rate of absorption of lidocaine differs by method, being greater with the aerosol and transtracheal techniques. The patient should be observed for signs of lidocaine toxicity (circumoral paresthesia, agitation, and seizures).

If adequate topical anesthesia cannot be achieved or if the patient is not cooperative, general anesthesia may be required for intubation. Table 8.4 lists common drugs and doses that are used to facilitate intubation. Ketamine and etomidate are two drugs that are used commonly because cardiovascular stability is maintained. Caution should be exercised when using etomidate in patients with signs and symptoms consistent with severe sepsis or septic shock. Owing to inhibition of 11β-hydroxylase, even a single dose of etomidate can cause adrenal suppression for up to 72 hours. Studies examining its use as an induction agent for intubation have reported inconsistent effects on mortality. Administration of corticosteroids after etomidate use is likely unnecessary. Use of opioids such as morphine, fentanyl, sufentanil, alfentanil, or remifentanil allows the dose of the induction drugs to be reduced and may attenuate the hemodynamic response to laryngoscopy and intubation. Muscle relaxants can be used to facilitate intubation, but unless the practitioner has extensive experience with these drugs and airway management, alternative means of airway control and oxygenation should be used until an anesthesiologist or other expert in airway management arrives to administer the anesthetic and performs the intubation. Although the use of muscle relaxants is associated with improved laryngoscopy grade during intubation, their use may not be associated with a decrease in overall airway-related complications, hypotension or hypoxemia.

Reviews have extolled the virtue of RSI [20]: the process by which a drug such as etomidate, thiopental, ketamine, or propofol (Table 8.4) is administered to the patient to induce anesthesia and is followed immediately by a muscle relaxant to facilitate intubation. Although numerous studies exist in the emergency medicine literature attesting to the safety and efficacy of this approach, the practitioner who embarks on
this route to intubation in the ICU must be knowledgeable about the pharmacology and side effects of the agents used, and the use of rescue methods should attempt(s) at intubation fail. Succinylcholine should be used cautiously because of its propensity to cause hyperkalemic cardiac arrest in certain critically ill populations, including burned and spinal injured patients. Prolonged bed rest can also lead to a hyperkalemic response after succinylcholine administration. This risk increases substantially if patients are in the ICU for more than 14 days [21]. Experience and an approached based on a validated algorithm will increase patient safety. In an analysis of 6,088 trauma patients undergoing emergency airway management in a single center over 10 years, intubation by anesthesiologists experienced in the management of trauma patients utilizing a modification of the American Society of Anesthesiologists difficult airway algorithm was very effective, resulting in a rate of surgical airway management in only 0.3% of patients included in the analysis [22].
TECHNIQUES OF INTUBATION

In a true emergency, some of the preintubation evaluation is necessarily neglected in favor of rapid control of the airway. Attempts at tracheal intubation should not cause or exacerbate hypoxia. Whenever possible, an oxygen saturation monitor should be used. Preoxygenation (denitrogenation), which replaces the nitrogen in the patient’s functional residual capacity with oxygen, can maximize the time available for intubation. During laryngoscopy, apneic oxygenation can occur from this reservoir. Preoxygenation is achieved by providing 100% oxygen at a high flow rate via a tight-fitting face mask for 3.5 to 4.0 minutes. Extending the time of preoxygenation from 4 to 8 minutes does not seem to increase the PaO$_2$ to a clinically relevant extent and may actually reduce the PaO$_2$ in the interval from 6 to 8 minutes in some patients [23]. In patients who are being intubated for airway control, preoxygenation is usually efficacious, whereas the value of preoxygenation in patients with acute lung injury is less certain [24]. Whenever possible, NIPPV or high flow nasal oxygen should be utilized as the mode of preoxygenation prior to intubation of hypoxemic patients. These approaches have been shown to be more effective than the standard approach in maintaining SpO$_2$ values before, during, and even after the intubation procedure [25–27]. In obese patients, the use of the 25-degree head-up position improves the effectiveness of preoxygenation.

Just before intubation, the physician should assess the likelihood of success for each route of intubation, the urgency of the clinical situation, the likelihood that intubation will be prolonged, and the prospect of whether diagnostic or therapeutic procedures such as bronchoscopy will eventually be required. Factors that can affect patient comfort should also be weighed. In the unconscious patient in whom a secure airway must be established immediately, orotracheal intubation with direct visualization of the vocal cords is generally the preferred technique. In the conscious patient, direct laryngoscopy or awake fiberoptic intubation may be performed after obtaining adequate anesthesia of the airway. Alternatively, blind nasotracheal intubation is an option but requires significant skill by the clinician. Nasotracheal intubation should be avoided in patients with coagulopathies or those who are anticoagulated for medical indications. In the obese patient, employing the ramped
position, whereby blankets are placed under the head, shoulders, and upper back to ensure that the tragus is at the level of the suprasternal notch, will increase the probability of a successful intubation (Fig. 8.11A and B). In trauma victims with extensive maxillary and mandibular fractures and inadequate ventilation or oxygenation, cricothyrotomy may be mandatory (see Chapter 9). In patients with cervical spine injury or decreased neck mobility, intubation using the flexible bronchoscope may be necessary. Many of these techniques require considerable skill and should be performed only by those who are experienced in airway management.

**FIGURE 8.11** A: Obese subject with head placed on pillow. The tragus is below the level of the suprasternal notch. B: After “ramping” with blankets beneath upper back and head, the tragus is at the level of the suprasternal notch.
Specific Techniques and Routes of Endotracheal Intubation

Orotracheal Intubation

Orotracheal intubation is the technique most easily learned and most often used for emergency intubations in the ICU. Traditional teaching dictates that successful orotracheal intubation requires alignment of the oral, pharyngeal, and laryngeal axes by putting the patient in the “sniffing position” in which the neck is flexed and the head is slightly extended about the atlanto-occipital joint. However, a magnetic resonance imaging (MRI) study has called this concept into question because the alignment of these three axes could not be achieved in any of the three positions tested: neutral, simple extension, and the “sniffing position” [28]. In addition, a randomized study in elective surgery patients examining the utility of the sniffing position as a means to facilitate orotracheal intubation failed to demonstrate that such positioning was superior to simple head extension [29,30].

In a patient with a full stomach, compressing the cricoid cartilage posteriorly against the vertebral body can reduce the diameter of the hypopharynx. This technique, known as Sellick maneuver, may prevent passive regurgitation of stomach contents into the trachea during intubation. However, an MRI study of awake volunteers demonstrated that the esophagus was lateral to the larynx in more than 50% of the subjects. Moreover, cricoid pressure increased the incidence of an unopposed esophagus by 50% and caused airway compression of greater than 1 mm in 81% of the volunteers [31]. These findings are in contrast to a more recent MRI study demonstrating that the location and movement of the esophagus is irrelevant to the efficacy of Sellick maneuver to prevent gastric regurgitation into the pharynx because the esophagus begins approximately 1 cm below the cricoid ring. In addition, the hypopharynx is attached to the cricoid ring by ligaments and muscles [32]. Consequently, compression of the alimentary tract was demonstrated with midline and lateral displacement of the cricoid cartilage relative to the underlying vertebral body [32]. Cadaver studies have demonstrated the efficacy of cricoid pressure [33], and clinical studies have shown that gastric insufflation with gas during mask ventilation is reduced when cricoid pressure is applied [34]. In aggregate, these data suggest that it is prudent to continue to use cricoid pressure in patients suspected of having full stomachs. In addition, placing the patient in the partial recumbent or reverse Trendelenburg position may reduce the risk of regurgitation and aspiration.

The laryngoscope handle is grasped in the left hand whereas the
patient’s mouth is opened with the gloved right hand. Often, when the head is extended in the unconscious patient, the mouth opens; if not, the thumb and index finger of the right hand are placed on the lower and upper incisors, respectively, and moved past each other in a scissor-like motion. The laryngoscope blade is inserted on the right side of the mouth and advanced to the base of the tongue, pushing it toward the left. If the straight blade is used, it should be extended below the epiglottis. If the curved blade is used, it is inserted in the vallecula.

With the blade in place, the operator should lift forward in a plane 45 degrees from the horizontal to expose the vocal cords (Figs. 8.2 and 8.9). This motion decreases the risk of the blade striking the upper incisors and either chipping or dislodging teeth. Both lips should be swept away from between the teeth and blade to avoid soft tissue damage. The ET tube is then held in the right hand and inserted at the right corner of the patient’s mouth in a plane that intersects with the laryngoscope blade at the level of the glottis. This prevents the ET tube from obscuring the view of the vocal cords. The ET tube is advanced through the vocal cords until the cuff just disappears from sight. The cuff is inflated with enough air to prevent a leak during positive-pressure ventilation with a bag valve device. Videos 8.1 and 8.2 of the technique are available at https://video.search.yahoo.com/video/play?p=New+England+Journal+of+Medicine+Intubation&vid=3d7ca1192ea871c2f64b8f9284b4ebb&turl=http%3A%2F%2Fts1.mm.bing.net%2Fth%3Fid%3DWN.Y0KiU0eOK9JsM7ZMbMzHVQ%26pid%3D15.1%26h%3D225%26w%3D300%26c%3D7%26rs%3D1&rurl=https%3A%2F%2Fwww.youtube.com%2Fwatch%3Fv%3D8SS_AhR-DUw&tit=Orotracheal+Intubation%2CPart-1&c=0&h=225&w=300&l=318&sigr=11btmomgp&sigt=10totfb98&sigi=12ku7qjn&ct=p&age=1325589995&fr2=p%3As%2Cv%3Av%26fr=yhs-mozilla-003&hsimp=yhs-003&hspart=mozilla&tt=b AND https://video.search.yahoo.com/video/play?p=New+England+Journal+of+Medicine+Intubation&vid=36d72b18a61e59101009ea1764b9eac3&turl=http%3A%2F%2Fts2.mm.bing.net%2Fth%3Fid%3DWN.ruA%252bnLZEtF3Fo0xeASQA%26pid%3D15.1%26h%3DD225%26w%3D300%26c%3D7%26rs%3D1&rurl=https%3A%2F%2Fwww.youtube.com%2Fwatch%3Fv%3D_c8lNoaP6Oo&tit=Orotracheal+Intubation%2C+part-2&c=1&h=225&w=300&l=409&sigr=11bkvot9h&sigt=10ototfb98&ct=p&age=1325760089&fr2=p%3As%2Cv%3Av%26fr=yhs-mozilla-003&hsimp=yhs-003&hspart=mozilla&tt=b; both accessed June 25, 2015.

Intubation using a videolaryngoscope is accomplished by holding the handle with the left hand and inserting the blade into the mouth and
advancing the tip to the vallecula (Fig. 8.12A, B and C). The view of the glottis is usually very good, but intubation can sometimes be problematic because the proprietary stylets are rigid and cannot be molded to the optimal curvature. Inserting the ET tube from the right at 90 degrees from the usual position may help if there is difficulty. Complications can include mucosal damage or perforation of the palatoglossal arch, palatopharyngeal arch, or the retromolar trigone. Direct visualization when inserting the tube into the mouth will reduce the risk of mucosal damage. (On-line tutorials are available: Turk M, Gravenstein D (2007): Storz DCI Video Laryngoscope, the University of Florida Department of Anesthesiology, Center for Simulation, Advanced Learning and Technology Web site: http://vam.anest.ufl.edu/airwaydevice/storz/index.html, accessed September 7, 2017 AND https://www.youtube.com/watch?v=4VAMBj2kc2Y, accessed September 7, 2017.)
A classification grading the view of the laryngeal aperture during direct laryngoscopy has been described[35] and is depicted in Figure 8.13. Occasionally, the vocal cords cannot be seen entirely; only the corniculate and cuneiform tubercles, interarytenoid incisure, and posterior portion of the vocal cords or only the epiglottis is visualized (grades II to IV view; Fig. 8.13). In this situation, it is helpful to insert the soft metal stylet into the ET tube and bend it into a hockey-stick configuration. The stylet should be bent or coiled at the proximal end to prevent the distal end from extending beyond the ET tube and causing tissue damage. The stylet should be lubricated to ensure easy removal. The BURP maneuver
(backward–upward–rightward pressure on the larynx) improves the view of the laryngeal aperture [36]. Alternatively, a control-tip ET tube can be used (Endotrol, Mallinckrodt, St. Louis, MO). This tube has a nylon cord running the length of the tube attached to a ring at the proximal end, which allows the operator to direct the tip of the tube anteriorly. Another aid is a stylet with a light (light wand). With the room lights dimmed, the ET tube containing the lighted stylet is inserted into the oropharynx and advanced in the midline. When it is just superior to the larynx, a glow is seen over the anterior neck. The stylet is advanced into the trachea, and the tube is threaded over it. The light intensity is diminished if the wand enters the esophagus (http://www.wakehealth.edu/School/Anesthesiology/Tutorials/Lightwand-Intubation-Tutorial.htm [accessed September 7, 2017]). The gum elastic bougie (flexible stylet) is another alternative device that can be passed into the larynx; once in place, the ET tube is advanced over it and the stylet is removed. ET tubes and stylets are now available that have a fiberoptic bundle intrinsic to the tube or the stylet that can be attached to a video monitor. If the attempt to intubate is still unsuccessful, the algorithm should be followed (see “Management of the Difficult Airway” section of this chapter).

**FIGURE 8.13** The four grades of laryngeal view during direct laryngoscopy. A: Grade I: the entire glottis is seen. B: Grade II: only the posterior aspect of the glottis is seen. C: Grade III: only the epiglottis is seen. D: Grade IV: the epiglottis is not visualized.

(From Cormack RS, Lehane J: Difficult tracheal intubation in obstetrics. Anaesthesia 39:1105–1111,
Proper depth of tube placement is clinically ascertained by observing symmetric expansion of both sides of the chest and auscultating equal breath sounds in both lungs. The stomach should also be auscultated to ensure that the esophagus has not been entered. If the tube has been advanced too far, it will lodge in one of the main bronchi (particularly the right bronchus), and only one lung will be ventilated. If this error goes unnoticed, the nonventilated lung may collapse. A useful rule of thumb for tube placement in adults of average size is that the incisors should be at the 23-cm mark in men and the 21-cm mark in women. Alternatively, proper depth (5 cm above the carina) can be estimated using the following formula: (height in cm/5) – 13 [37]. Palpation of the anterior trachea in the neck may detect cuff inflation because air is injected into the pilot tube and can serve as a means to ascertain correct tube position. Measurement of end-tidal carbon dioxide by standard capnography if available or by means of a calorimetric chemical detector of end-tidal carbon dioxide (e.g., Easy Cap II, Nellcor, Inc., Pleasanton, CA) should be used to verify correct ET tube placement or detect esophageal intubation. The latter device is attached to the proximal end of the ET tube and changes color on exposure to carbon dioxide. An additional method to detect esophageal intubation uses a bulb that attaches to the proximal end of the ET tube (AMBU, Ballerup, Denmark). The bulb is squeezed. If the tube is in the trachea, the bulb reexpands, and if the tube is in the esophagus, the bulb remains collapsed. It must be remembered that none of these techniques is fool proof. Bronchoscopy is the only method to be absolutely sure the tube is in the trachea. After estimating proper tube placement clinically, it should be confirmed by chest radiograph or bronchoscopy because the tube may be malpositioned. The tip of the ET tube should be several centimeters above the carina (T-4 level). It must be remembered that flexion or extension of the head can advance or withdraw the tube 2 to 5 cm, respectively.

Nasotracheal Intubation

Many of the considerations concerning patient preparation and positioning outlined for orotracheal intubation apply to nasal intubation as well. Blind nasal intubation is more difficult to perform than oral intubation because the tube cannot be observed directly as it passes between the vocal cords. Nasal intubation should not be attempted in patients with abnormal bleeding parameters, nasal polyps, extensive
facial trauma, cerebrospinal rhinorrhea, sinusitis, or any anatomic abnormality that would inhibit atraumatic passage of the tube. Nasal intubation is rarely performed because of the risk of maxillary sinusitis.

As previously discussed in “Airway Adjuncts” section, after the operator has alternately occluded each nostril to ascertain that both are patent, a topical vasoconstrictor and anesthetic are applied to the nostril that will be intubated. The nostril may be dilated with lubricated nasal airways of increasing size to facilitate atraumatic passage of the ET tube. The patient should be monitored with a pulse oximeter, and supplemental oxygen should be given as necessary. The patient may be either supine or sitting with the head extended in the sniffing position. The tube is guided slowly but firmly through the nostril to the posterior pharynx. Here the tube operator must continually monitor for the presence of air movement through the tube by listening for breath sounds with the ear near the open end of the tube. The tube must never be forced or pushed forward if breath sounds are lost, because damage to the retropharyngeal mucosa can result. If resistance is met, the tube should be withdrawn 1 to 2 cm and the patient’s head repositioned (extended further or turned to either side). If the turn still cannot be negotiated, the other nostril or a smaller tube should be tried. Attempts at nasal intubation should be abandoned and oral intubation performed if these methods fail.

Once positioned in the oropharynx, the tube is advanced to the glottis while listening for breath sounds through the tube. If breath sounds cease, the tube is withdrawn several centimeters until breath sounds resume, and the plane of entry is adjusted slightly. Inflation of the cuff will facilitate alignment of the ET tube with the glottis. Passage through the vocal cords should be timed to coincide with inspiration. Entry of the tube into the larynx is signalled by an inability to speak. The cuff should be inflated and proper positioning of the tube ascertained as previously outlined.

Occasionally, blind nasal intubation cannot be accomplished. In this case, after adequate topical anesthesia, laryngoscopy can be used to visualize the vocal cords directly and Magill forceps used to grasp the distal end of the tube and guide it through the vocal cords. Assistance in pushing the tube forward is essential during this maneuver so that the operator merely guides the tube. The balloon on the tube should not be grasped with the Magill forceps.

**Management of the Difficult Airway**
A difficult airway may be recognized (anticipated) or unrecognized at the time of the initial preintubation airway evaluation. Difficulty managing the airway may be the result of abnormalities such as congenital hypoplasia, hyperplasia of the mandible or maxilla, or prominent incisors; injuries to the face or neck; acromegaly; tumors; and previous head and neck surgery. Difficulties ventilating the patient with a mask can be anticipated if two of the following factors are present: older than 55 years of age, body mass index greater than 26 kg per m², beard, lack of teeth, and a history of snoring [38]. When a difficult airway is encountered, the algorithm as detailed in Figure 8.14 should be followed. When a difficult airway is recognized before the patient is anesthetized, an awake tracheal intubation is usually the best option. Multiple techniques can be used and include (after adequate topical or local anesthesia) direct laryngoscopy, LMA (or variants), blind or bronchoscopic oral or nasal intubation, retrograde technique, rigid bronchoscopy, lighted stylet, or a surgical airway.

**Algorithm for airway management in the ICU**

- **Airway management necessary**

    - Primary awake technique (FOI, nasotracheal)

**Figure 8.14** Modification of the difficult airway algorithm. ASA DAA, American Society of Anesthesiologists difficult airway algorithm; DMV,
Flexible Bronchoscopic Intubation

Flexible bronchoscopy is an efficacious method of intubating the trachea in difficult cases. It may be particularly useful when the upper airway anatomy has been distorted by tumors, trauma, endocrinopathies, or congenital anomalies. This technique is sometimes valuable in accident victims in whom a question of cervical spine injury exists and the patient’s neck cannot be manipulated. An analogous situation exists in patients with severe degenerative disk disease of the neck or rheumatoid arthritis with markedly impaired neck mobility. After adequate topical anesthesia is obtained (discussed in “Anesthesia before Intubation” section), the bronchoscope can be used to intubate the trachea via either the nasal or oral route. An appropriately sized warmed and lubricated ET tube that has been preloaded onto the bronchoscope is advanced through the vocal cords into the trachea and positioned above the carina under direct vision. The flexible bronchoscope has also been used as a stent over which ET tubes are exchanged and as a means to assess tracheal damage periodically during prolonged intubations. (A detailed discussion of bronchoscopy is found in Chapter 10.) Intubation by this technique requires skill and experience and is best performed by a fully trained operator.

If the operator is able to maintain mask ventilation in a patient with an unrecognized difficult airway, a call for experienced help should be initiated (Fig. 8.14). If mask ventilation cannot be maintained, a cannot ventilate–cannot intubate situation exists and immediate lifesaving rescue maneuvers are required. Options include an emergency cricothyrotomy or insertion of a supraglottic ventilatory device, such as an LMA or a Combitube (Puritan Bennett, Pleasanton, CA).

Other Airway Adjuncts

The LMA is composed of a plastic tube attached to a shallow mask with an inflatable rim (Fig. 8.15A–D). When properly inserted, it fits over the
laryngeal inlet and allows positive-pressure ventilation of the lungs. Although aspiration can occur around the mask, the LMA can be lifesaving in a cannot ventilate–cannot intubate situation. An intubating LMA (LMA-Fastrach; LMA North America, Inc., San Diego, CA) has a shorter plastic tube and can be used to provide ventilation as well as to intubate the trachea with or without the aid of a flexible bronchoscope (Fig. 8.16). The Combitube (Puritan Bennett) combines the features of an ET tube and an esophageal obturator airway and reduces the risk of aspiration. Personnel who are unskilled in airway management can easily learn how to use the LMA and the Combitube together.
FIGURE 8.15 A–D: Technique for insertion of the laryngeal mask airway.
(Reproduced with permission from Janet Fong.)
FIGURE 8.16 The laryngeal mask airway (LMA)-Fastrach (A) has a shorter tube than a conventional LMA. A special endotracheal tube (B) (without the adapter (C)) is advanced through the LMA-Fastrach into the trachea. The extender (D) is attached to the endotracheal tube, and the LMA-Fastrach is removed. After the extender is removed, the adapter is placed back on the tube.

Cricothyrotomy

In a truly emergent situation, when intubation is unsuccessful, a cricothyrotomy may be required. The technique is described in detail in Chapter 9. The quickest method, needle cricothyrotomy, is accomplished by introducing a large-bore (i.e., 14-gauge) catheter into the airway through the cricothyroid membrane while aspirating with a syringe attached to the needle of the catheter. When air is aspirated, the needle is in the airway, and the catheter is passed over the needle into the trachea. The needle is attached to a high-frequency jet ventilation apparatus. Alternatively, a 3-mL syringe barrel can be connected to the catheter. Following this, a 7-mm inside diameter ET tube adapter is fitted into the syringe and is connected to a high-pressure gas source or a high-frequency jet ventilator. As mentioned previously, identification of the cricothyroid membrane by palpation may be difficult. An algorithm with
suggestions for the management of the difficult airway is provided in Figure 8.14.

Management of the Airway in Patients with Suspected Cervical Spine Injury

Any patient with multiple trauma who requires intubation should be treated as if cervical spine injury was present. In the absence of severe maxillofacial trauma or cerebrospinal rhinorrhea, nasal intubation can be considered. However, in the profoundly hypoxemic or apneic patient, the orotracheal approach should be used. If oral intubation is required, an assistant should maintain the neck in the neutral position by ensuring axial stabilization of the head and neck because the patient is intubated. A cervical collar also assists in immobilizing the cervical spine. Videolaryngoscopy provides a better view of the glottis in this situation. However, with the exception of the Airtraq device (Airtraq, www.airtraq.com), intubation on the first attempt is not improved with videolaryngoscopy compared to use of the MacIntosh blade [39]. In a patient with maxillofacial trauma and suspected cervical spine injury, retrograde intubation can be performed by puncturing the cricothyroid membrane with an 18-gauge catheter and threading a 125-cm Teflon-coated (0.025-cm diameter) guidewire through the catheter. The wire is advanced into the oral cavity, and the ET tube is then advanced over the wire into the trachea. Alternatively, the wire can be threaded through the suction port of a 3.9-mm bronchoscope.

Airway Management in the Intubated Patient

Securing the Tube

Properly securing the ET tube in the desired position is important for three reasons: (a) to prevent accidental extubation, (b) to prevent advancement into one of the main bronchi, and (c) to minimize damage to the upper airway, larynx, and trachea caused by patient motion. The ET tube is usually secured in place with adhesive tape wrapped around the tube and applied to the patient’s cheeks. Tincture of benzoin sprayed on the skin provides greater fixation. Alternatively, tape, intravenous (IV) tubing, or umbilical tape, can be tied to the ET tube and brought around the patient’s neck to secure the tube. Care must be taken to prevent occlusion of neck veins. Other products (e.g., Velcro straps) to secure the tube are available. A bite block can be positioned in patients who are orally intubated to prevent them from biting down on the tube and occluding it. Once the tube has been secured and its proper position
verified, it should be plainly marked on the portion protruding from the patient’s mouth or nose so that advancement can be noted.

**Cuff Management**

Although low-pressure cuffs have markedly reduced the incidence of complications related to tracheal ischemia, monitoring cuff pressures remains important. The cuff should be inflated just beyond the point where an audible air leak occurs. Maintenance of intracuff pressures between 17 and 23 mm Hg should allow an adequate seal to permit mechanical ventilation under most circumstances while not compromising blood flow to the tracheal mucosa. The intracuff pressure should be checked periodically by attaching a pressure gauge and syringe to the cuff port via a three-way stopcock. The need to add air continually to the cuff to maintain its seal with the tracheal wall indicates that (a) the cuff or pilot tube has a hole in it, (b) the pilot tube valve is broken or cracked, or (c) the tube is positioned incorrectly, and the cuff is between the vocal cords. The tube position should be reevaluated to exclude the latter possibility. If the valve is broken, attaching a three-way stopcock to it will solve the problem. If the valve housing is cracked, cutting the pilot tube and inserting a blunt needle with a stopcock into the lumen of the pilot tube can maintain a competent system. A hole in the cuff necessitates a change of tube.

**Tube Suctioning**

A complete discussion of tube suctioning can be found in Chapter 169. Routine suctioning should not be performed in patients in whom secretions are not a problem. Suctioning can produce a variety of complications, including hypoxemia, elevations in intracranial pressure, and serious ventricular arrhythmias. Preoxygenation should reduce the likelihood of arrhythmias. Closed ventilation suction systems (Stericath) may reduce the risk of hypoxemia but have not been shown to reduce the rate of ventilator-associated pneumonia compared to open suction systems [40].

**Humidification**

Intubation of the trachea bypasses the normal upper airway structures responsible for heating and humidifying inspired air. It is thus essential that inspired air be heated and humidified (see Chapter 169).

**Tube Replacement**
At times, ET tubes may need to be replaced because of an air leak, obstruction, or other problems. Obstruction can be relieved with balloon-tipped catheters. The catheter is inserted into the tube and advanced to the tip, and the balloon is inflated. The catheter is pulled back, and the obstructing debris is dislodged from the tube. Before attempting to change an ET tube, one should assess how difficult it will be. After ensuring appropriate nil per os status, obtaining appropriate topical anesthesia or IV sedation and achieving muscle relaxation, direct laryngoscopy can be performed to ascertain whether there will be difficulties in visualizing the vocal cords. If the cords can be seen, the defective tube is removed under direct visualization and reintubation is performed using the new tube. If the cords cannot be seen on direct laryngoscopy, the tube can be changed over an airway exchange catheter (e.g., Cook Critical Care, Bloomington, IN) which allows insufflation of oxygen via either standard oxygen tubing or a bag valve device [41].
COMPLICATIONS OF ENDOTRACHEAL INTUBATION

Table 8.4 is a partial listing of the complications associated with ET intubation. Factors implicated in the etiology of complications include tube size, characteristics of the tube and cuff, trauma during intubation, duration and route of intubation, metabolic or nutritional status of the patient, tube motion, and laryngeal motor activity.

TABLE 8.5 Complications of Endotracheal Intubation

Complications during intubation
- Spinal cord injury
- Excessive delay of cardiopulmonary resuscitation
- Aspiration
- Damage to teeth and dental work
- Corneal abrasions
- Perforation or laceration of
  - Pharynx
  - Larynx
  - Trachea
- Dislocation of an arytenoid cartilage
- Passage of endotracheal tube into cranial vault
- Epistaxis
- Cardiovascular problems
  - Ventricular premature contractions
  - Ventricular tachycardia
  - Bradyarrhythmias
  - Hypotension
  - Hypertension
  - Hypoxemia

Complications while tube is in place
- Blockage or kinking of tube
- Dislodgment of tube
Advancement of tube into a bronchus
Mechanical damage to any upper airway structure
Problems related to mechanical ventilation (see Chapter 166)

Complications following extubation
Immediate complications
Laryngospasm
Aspiration

Intermediate- and long-term complications
Sore throat
Ulcerations of lips, mouth, pharynx, or vocal cords
Tongue numbness (hypoglossal nerve compression)
Laryngitis
Vocal cord paralysis (unilateral or bilateral)
Laryngeal edema
Laryngeal ulcerations
Laryngeal granuloma
Vocal cord synechiae
Tracheal stenosis

During ET intubation, traumatic injury can occur to any anatomic structure from the lips to the trachea. Possible complications include aspiration; damage to teeth and dental work; corneal abrasions; perforation or laceration of the pharynx, larynx, or trachea; dislocation of an arytenoid cartilage; retropharyngeal perforation; epistaxis; hypoxemia; myocardial ischemia; laryngospasm with noncardiogenic pulmonary edema; and death [2,3]. Many of these complications can be avoided by paying careful attention to technique and ensuring that personnel with the greatest skill and experience perform the intubation. Complications during ET intubation vary according to the location of the patient in need of emergency airway management. Although the complication rates on the regular hospital floor and in the ICU appear to be high at around 28% for both locations, they can be modified with standardized algorithms as outlined previously. The most frequent complications encountered in these two settings are multiple intubation attempts and esophageal intubation in the general hospital units, and severe hypoxemia and hemodynamic collapse in the ICU. The presence of acute respiratory failure and shock appears to be an independent risk factor for the occurrence of complications in the latter setting [42,43].
Complications During Intubation

A variety of cardiovascular complications can accompany intubation. Ventricular arrhythmias have been reported in 5% to 10% of intubations. Ventricular tachycardia and ventricular fibrillation are uncommon but have been reported. Patients with myocardial ischemia are susceptible to ventricular arrhythmias, and lidocaine prophylaxis (100 mg IV bolus) before intubation may be warranted in such individuals. Bradyarrhythmias can also be observed and are probably caused by stimulation of the laryngeal branches of the vagus nerve. They may not require therapy but usually respond to IV atropine (1 mg IV bolus). Hypotension or hypertension can occur during intubation. In the patient with myocardial ischemia, short-acting agents to control blood pressure (nitroprusside and nicardipine) and heart rate (esmolol) during intubation may be needed.

Complications While the Tube is in Place

Despite adherence to guidelines designed to minimize damage from ET intubation, the tube can damage local structures. Microscopic alterations to the surface of the vocal cords can occur within 2 hours after intubation. Evidence of macroscopic damage can occur within 6 hours. As might be expected, clinically significant damage typically occurs when intubation is prolonged. The sudden appearance of blood in tracheal secretions suggests anterior erosion into overlying vascular structures, and the appearance of gastric contents suggests posterior erosion into the esophagus. Both situations require urgent bronchoscopy, and it is imperative that the mucosa underlying the cuff be examined. Other complications include tracheomalacia and stenosis and damage to the larynx. Failure to secure the ET tube properly or patient agitation can contribute to mechanical damage.

Another complication is blockage or kinking of the tube, resulting in compromised ventilation. Placing a bite block in the patient’s mouth can minimize occlusion of the tube caused by the patient biting down on it. Suctioning can usually solve blockage from secretions, although changing the tube may be necessary.

Unplanned extubation and endobronchial intubation are potentially life threatening. Judicious use of sedatives and analgesics and appropriately securing and marking the tube can minimize these problems. Other complications that occur while the tube is in position relate to mechanical ventilation (e.g., pneumothorax) and are discussed in detail in Chapter 58.

Complications After Extubation
Sore throat occurs after 40% to 100% of intubations. Using a smaller ET tube may decrease the incidence of postextubation sore throat and hoarseness. Ulcerations of the lips, mouth, or pharynx can occur and are more common if the initial intubation was traumatic. Pressure from the ET tube can traumatize the hypoglossal nerve, resulting in numbness of the tongue that can persist for 1 to 2 weeks. Irritation of the larynx appears to be caused by local mucosal damage and occurs in as many as 45% of individuals after extubation. Unilateral or bilateral vocal cord paralysis is an uncommon but serious complication following extubation.

Some degree of laryngeal edema accompanies almost all ET intubations. In adults, this is usually clinically insignificant. In children, however, even a small amount of edema can compromise the already small subglottic opening. In a newborn, 1 mm of laryngeal edema results in a 65% narrowing of the airway. Laryngeal ulcerations are commonly observed after extubation. They are more commonly located at the posterior portion of the vocal cords, where the ET tube tends to rub. Ulcerations become increasingly common the longer the tube is left in place. The incidence of ulceration is decreased by the use of ET tubes that conform to the anatomic shape of the larynx. Laryngeal granulomas and synechiae of the vocal cords are extremely rare, but these complications can seriously compromise airway patency. Surgical treatment is often required to treat these problems.

A feared late complication of ET intubation is tracheal stenosis. This occurs much less frequently now that high-volume, low-pressure cuffs are routinely used. Symptoms can occur weeks to months after extubation. In mild cases, the patient may experience dyspnea or ineffective cough. If the airway is narrowed to less than 5 mm, the patient presents with stridor. Dilation may provide effective treatment, but, in some instances, surgical intervention is necessary.
EXTUBATION

The decision to extubate a patient is based on (a) a favorable clinical response to a carefully planned regimen of weaning from mechanical ventilation (see Chapter 168), (b) recovery of consciousness following anesthesia, or (c) sufficient resolution of the initial indications for intubation.

Technique of Extubation

The patient should be alert, lying with the head of the bed elevated to at least a 45-degree angle. The posterior pharynx must be thoroughly suctioned. The procedure is explained to the patient. The cuff is deflated, and positive pressure is applied to expel any foreign material that has collected above the cuff as the tube is withdrawn. Supplemental oxygen is then provided.

In situations in which postextubation difficulties are anticipated, equipment for emergency reintubation should be assembled at the bedside. In addition, administration of preextubation steroids will reduce the risk of developing stridor [44]. Some clinicians have advocated the “leak test” as a means to predict the risk of stridor after extubation. The utility of this procedure is limited in routine practice, but for patients with certain risk factors (e.g., traumatic intubation, prolonged intubation, and previous accidental extubation), a leak volume of greater than 130 mL or 12% of the tidal volume has a sensitivity and specificity of 85% and 95%, respectively, for the development of postextubation stridor [45]. Probably, the safest way to extubate the patient if there are concerns about airway edema or the potential need to reintubate a patient with a difficult airway is to use an airway exchange catheter. This device is inserted through the ET tube and then the tube is removed over the catheter. Supplemental oxygen can be provided via the catheter to the patient, and the catheter can be used as a stent for reintubation if necessary.

One of the most serious complications of extubation is laryngospasm, and it is more likely to occur if the patient is not fully conscious. The application of positive pressure can sometimes relieve laryngospasm. If this maneuver is not successful, a small dose of succinylcholine (by the IV or intramuscular route) can be administered. Succinylcholine can cause severe hyperkalemia in a variety of clinical settings; therefore, only clinicians who are experienced with its use should administer it. Ventilation with a mask and bag unit is needed until the patient has recovered from the succinylcholine.
Tracheostomy

The optimal time of conversion from an ET tube to a tracheostomy remains controversial. The reader is referred to Chapter 9 for details on tracheostomy.

Utility of Ultrasonography for Airway Management

Ultrasonography has several useful applications related to airway management.

Identification of Gastric Fluid

Ultrasonography examination of the stomach is a useful means of identifying gastric contents [46]. Identification of a full stomach during setup for urgent ET intubation allows the team to avoid the catastrophic complication of massive aspiration during urgent ET intubation sequence. A proficient operator can scan for gastric contents in less than 1 minute, so the examination is feasible as a routine safety measure during urgent ET intubations. With the phased array probe configured for abdominal scanning, the examination is performed with longitudinal (coronal) scanning plane over the lower left lateral thorax in the midaxillary line. The tomographic ultrasonography plane is angled through the target area. The spleen maybe used as a sonographic window. An alternative method is to examine the left upper quadrant from the anterior approach, although gas artifact frequently blocks adequate imaging. If significant gastric fluid is present (Video 8.3), the team may elect to insert a gastric tube to empty the stomach. If the patient is so unstable that this is not possible, the team, alerted to the risk of massive aspiration, may take specific steps to reduce this risk, such as utilization of a paralytic agent, preparing extra suction devices, and assigning the intubation to the team member with highest skill level.

Identification of Endotracheal Tube Position

Ultrasonography may be used to verify the position of the ET tube [47,48]. The high-frequency vascular transducer is used to obtain a transverse-axis image of the trachea immediately above the suprasternal notch (Video 8.4). The anterior wall of the trachea appears as a curvilinear echogenic line often in association with a posterior comet tale artifact. With real-time scanning, the ET tube may be seen to pass through the image plane into the trachea or into the adjacent esophagus appearing as an echogenic line within the boundaries of the trachea. Alternatively, the operator may opt to identify ET tube position
immediately following the insertion of the ET tube. The esophagus is usually immediately posterior and to the left of the trachea. Less commonly, it is to the right or posterior to the trachea. In case of unintentional esophageal intubation, the ET tube is visualized in transverse scanning plane posterior and usually to the left of the laryngeal structures. One limitation of ultrasonography of the trachea for ET tube placement is that, if there is air interposed between the anterior tracheal wall and the ET tube, the air will block visualization of the ET tube. For this reason, visualization of the ET tube within the trachea should only be used when other standard techniques of verification are not immediately available or deemed unreliable for clinical reasons.

Ultrasonography may be used to indirectly infer ET tube position using lung ultrasonography. Instead of directly identifying the position of the tube in the airway, successful ET intubation is verified by the presence of bilateral lung sliding, which may be rapidly ascertained by examination for lung sliding during bag valve breaths [49] (see Chapter 11 on Lung Ultrasonography). The combination of direct visualization methods described earlier with lung sliding has been reported to have very high predictive value for identification successful ET tube insertion [50].

Ultrasonography may be used to rapidly identify the presence of a right mainstem intubation [51]. In this case, the inflated ET tube cuff may block off the left mainstem bronchus with persistent hypoxemia and rapid resorptive atelectasis of the left lung. As a result, lung sliding will be present on the right side but absent on the left side. The ET tube may be pulled back under ultrasonography control until lung sliding is observed bilaterally.
REFERENCES

...

Tracheostomy first started to be performed regularly in the 1800s when used by Trousseau and Bretonneau in the management of diphtheria. In the early 1900s, this procedure was used to treat difficult cases of respiratory paralysis from poliomyelitis. Largely because of improvements in tubes and advances in clinical care, endotracheal intubation has become the treatment of choice for short-term airway management.

Although urgent tracheostomy or emergent cricothyrotomy is occasionally required in critically ill and injured patients who cannot be intubated for various reasons (e.g., cervical spine injury, upper airway obstruction, laryngeal injury, and anatomic considerations), the most common use of this procedure today is to provide long-term access to the airway in patients who are dependent on mechanical ventilation. With improvements in critical care medicine over the past 30 years, more patients are surviving their initial episodes of acute respiratory failure, trauma, and extensive surgeries, and require prolonged periods of mechanical ventilation. It is now common practice to convert these patients from translaryngeal intubation to tracheostomy. Tracheostomy is becoming a common procedure in the intensive care unit (ICU). The prevalence of tracheostomies in ICU patients ranges from 8% to more than 30% [1,2].

In this chapter, we review the indications, contraindications, complications, and techniques associated with tracheostomy. We also discuss the timing of converting from translaryngeal intubation to a tracheostomy.

INDICATIONS
The indications for tracheostomy can be divided into three general categories: (1) to bypass obstruction of the upper airway, (2) to provide an avenue for removal of secretions retained in the airways, and (3) to provide a means for prolonged ventilatory support. These indications are summarized in Table 9.1 [3,4].

Anticipated prolonged ventilatory support, especially for patients receiving mechanical ventilation via translaryngeal intubation, is the most common indication for placing a tracheostomy in the ICU. There are several advantages and disadvantages of both translaryngeal intubation and tracheostomy in patients requiring prolonged ventilator support, and these are summarized in Table 9.2 [4–6]. Most authors feel that when the procedure is performed by a skilled specialist, the potential benefits of tracheostomy over translaryngeal intubation for most patients justify the application despite its potential risks. However, there are no detailed prospective clinical trials rigorously evaluating the advantages of tracheostomy in patients requiring prolonged mechanical ventilation. In a retrospective and a nonrandomized study, there were conflicting data on mortality in patients with respiratory failure of more than 1 week with
regard to receiving a tracheostomy or continuing with an endotracheal tube [1,2].

| More secure airway                               | Surgical scar                                  |
| Improved patient comfort                         | Tracheal and stomal stenosis                  |
| Permits speech                                   |                                                |
| Provides psychologic benefit                     |                                                |
| More rapid weaning from mechanical ventilation   |                                                |
| Better oral hygiene                             |                                                |
| Decreased risk of nosocomial pneumonia           |                                                |
CONTRAINDICATIONS

There are no absolute contraindications to tracheostomy. Relative complications include uncorrected coagulopathy, high levels of ventilator support (i.e., high levels of positive end-expiratory pressure [PEEP]), and abnormal anatomy of the upper airway. However, a prospective cohort study has demonstrated that percutaneous tracheostomy can be safely preformed in patients with refractory coagulopathy from liver disease [7]. Morbidly obese patients with body mass index greater than 30 kg per m\(^2\) also appear to be at higher risk for complications with both open tracheostomy [8] and possibly percutaneous tracheostomy [9]. In patients with severe brain injury, percutaneous tracheostomy can be safely performed without significantly further increasing intracranial pressure [10].

Certain conditions warrant special attention. In patients undergoing conversion from translaryngeal intubation to a tracheostomy for prolonged ventilatory support, the procedure should be viewed as an elective or semielective procedure. Therefore, the patient should be optimally physiologically stabilized before the procedure, and all attempts should be made to correct coagulopathies, including uremia. The patient should tolerate submaximal ventilator settings because during the exchange positive pressure is lost temporarily. If not already on low levels (5 cm H\(_2\)O) of PEEP, placing the patient supine and using 5 or 7.5 cm H\(_2\)O of PEEP temporarily is a good test to decide if the patient will tolerate the exchange. Emergent tracheostomies for upper airway obstruction may need to be performed when the patient is unstable or has a coagulopathy.
TIMING OF TRACHEOSTOMY

Recommendations on when to perform a tracheostomy on an intubated, critically ill patient have varied over time. However, with the release of some consistent and recent studies, more sound recommendations can be made. Table 9.3 summarizes several studies comparing early versus late tracheostomy [11–21]. In 2003, Heffner recommended consideration of tracheostomy if a patient remains ventilator dependent after a week of translaryngeal intubation. If the patient has barriers to weaning and appears unlikely to be extubated within 7 days, a tracheostomy should be performed. Conversely, if the patient has minimal barriers to weaning and is likely to be extubated within 7 days, tracheostomy should be avoided. In those whose status is unclear, the need for tracheostomy should be readdressed daily [4].

Subsequently, a meta-analysis in 2005 [11] suggested advantages to “early tracheostomy” performed within 7 days of translaryngeal intubation over a “late tracheostomy” (>7 days) in critically ill patients requiring mechanical ventilation. The meta-analysis combined five prospective studies and included 406 patients and suggested that early tracheostomy resulted in a decrease in length of ICU stay by an average of 15.3 days and a decrease in duration of mechanical ventilation by an average of 8.5 days [11]. Potential reasons for the decrease in duration of mechanical ventilation include easier weaning due to less dead space; lower airflow resistance; and less frequent episodes of obstruction due to mucus plugging in patients with tracheostomies. There was no significant increase in hospital mortality or risk of hospital-acquired pneumonia. However, there were limitations to the meta-analysis, including the inclusion of insufficiently randomized studies. Since this meta-analysis, multiple randomized controlled studies have been published which have consistently contradicted these results [20]. A subsequent 2011 meta-analysis of seven randomized controlled studies which included 1,044 patients showed no difference in mortality, mechanical ventilator days, or ICU length of stay [20]. More recently, in a study performed in the UK, 909 adult patients with respiratory failure not attributed to chronic neurologic disease were randomized to undergo “early” tracheostomy performed within 4 days of intubation, or “late” tracheostomy as defined by after 10 days if still indicated. Patients were identified by Intensive Care Day 4, as likely to require mechanical ventilation for at least an additional 7 days, and subsequently randomized to either group. There was no difference in 30-day, 1-year, or 2-year mortality between groups.
Median critical care unit length of stay and need for antibiotics were similar in the groups, whereas the median days of intravenous sedation was lower in the early group: 5 versus 8 days, \( p < 0.001 \) [21]. Interestingly, tracheostomy was avoided in 53.7% in the late group, suggesting that identification of patients who will require long-term ventilation is not clear-cut [21].

In summary, despite previous research suggesting otherwise, the benefits of “early” tracheostomy are not sufficient to recommend tracheostomy prior to 7 to 10 days of translaryngeal intubation. Delayed tracheostomy likely leads to avoidance of tracheostomy in many patients, and correspondingly avoidance of potential complications associated with the procedure.

Early tracheostomy may be beneficial in some specific instances; however, the majority of the data is based on retrospective studies. Patients with blunt, multiple-organ trauma have a shorter duration of mechanical ventilation, fewer episodes of nosocomial pneumonia [22], and a significant reduction in hospital costs [23] when the tracheostomy is performed within 1 week of their injuries. Similar benefits have been reported in patients with head trauma and poor Glasgow Coma Score [24], acute spine trauma [25], and thermal injury [26] if a tracheostomy is performed within a week after the injury. Also, patients with facial injuries may require early tracheostomy to allow or facilitate facial fracture surgery, fixation, and immobilization.
PROCEDURES

Emergency Tracheostomy

Emergency tracheostomy is a moderately difficult procedure requiring training and skill, experience, adequate assistance, time, lighting, and proper equipment and instrumentation. When time is short, the patient is uncooperative, anatomy is distorted, and the aforementioned requirements are not met, then tracheostomy can be very hazardous. Emergency tracheostomy comprises significant risks to nearby neurovascular structures, particularly in small children in whom the trachea is small and not well defined. The risk of complications from emergency tracheostomy is two to five times higher than for elective tracheostomy [27,28]. Nonetheless, there are occasional indications for emergency tracheostomy [29], including transected trachea; anterior neck trauma with crushed larynx [30]; severe facial trauma; acute laryngeal obstruction or near-impending obstruction; and pediatric (younger than 12 years) patients requiring an emergency surgical airway in whom a cricothyrotomy is generally not advised. In emergency situations, when there is inadequate time or personnel to perform an emergency tracheostomy, a cricothyrotomy may be a more efficient and expedient manner to provide an airway.

Cricothyrotomy

Although initially condemned because of a high rate of complications, cricothyrotomy may have some potential advantages over tracheostomy. These include technical simplicity; speed of performance; low complication rate [31]; suitability as a bedside procedure; usefulness for isolation of the airway for median sternotomy and radical neck dissection [32]; lack of need to hyperextend the neck; and formation of a smaller scar. Also, because cricothyrotomy results in less encroachment on the mediastinum, there is less chance of esophageal injury and virtually no chance of pneumothorax or tracheal arterial fistula [33]. Despite these considerations, many authorities currently recommend that cricothyrotomy be used as an elective long-term method of airway access only in highly selected patients [34]. Use of cricothyrotomy in the emergency setting, particularly for managing trauma, is not controversial [35–37]. Emergency cricothyrotomy is useful because it requires a small number of instruments and less training than tracheostomy, and can be performed quickly as indicated as a means of controlling the airway in an emergency when oral or nasotracheal intubation is nonsuccessful or
contraindicated. The cricothyroid membrane is higher in the neck than
the tracheal rings and therefore closer to the surface and more accessible.
In emergency situations, translaryngeal intubations fail because of
massive oral or nasal hemorrhage or regurgitation; structural deformities
of the upper airway; muscle spasm and clenched teeth; and obstruction
by foreign body through the upper airway [35]. Cricothyrotomy finds its
greatest use in trauma management, axial or suspected cervical spine
injury, alone or in combination with severe facial trauma, where
nasotracheal and orotracheal intubation is both difficult and hazardous.
Thus, cricothyrotomy has an important role in emergency airway
management [36].

Use and Contraindications

Cricothyrotomy should not be used to manage airway obstruction that
occurred immediately after endotracheal extubation because the
obstruction may be found below the larynx [36]; likewise, with primary
laryngeal trauma or diseases such as a tumor or an infection,
cricothyrotomy may prove to be useless. It is contraindicated in infants
and children younger than 10 to 12 years under all circumstances because
stenosis and even transection are possible [36]. In this age group,
percutaneous needle catheter transtracheal ventilation may be a
temporizing procedure until the tracheostomy can be performed.

Anatomy

The cricothyroid space is no larger than 7 to 9 mm in its vertical
dimension, smaller than the outside diameter of most tracheostomy tubes
(outside diameter 10 mm). The cricothyroid artery runs across the
midline in the upper portion, and the membrane is vertically in the
midline. The anterior superior edge of the thyroid cartilage is the
laryngeal prominence. The cricothyroid membrane is approximately 2 to
3 cm below the laryngeal prominence and can be identified as an
indentation immediately below the thyroid cartilage. The lower border of
the cricothyroid membrane is the cricoid cartilage [33,35]. A description
of the cricothyrotomy procedure is contained in standard surgical texts.
well-controlled, carefully selected cases to greater than 50% for procedures performed under emergency or other suboptimal conditions [3,36]. The incidence of subglottic stenosis after cricothyrotomy is 2% to 3% [3,31]. This major complication occurs at the tracheostomy or cricothyrotomy site, but not at the cuff site [38]. Necrosis of cartilage due to iatrogenic injury to the cricoid cartilage or pressure from the tube on the cartilage may play a role [37]. Possible reasons that subglottic stenoses may occur more commonly with cricothyrotomy than with tracheostomy are as follows: the larynx is the narrowest part of the laryngotracheal airway; subglottic tissues, especially in children, are intolerant of contact; and division of the cricothyroid membrane and cricoid cartilage destroy the only complete rings supporting the airway. Furthermore, the range of tube sizes is limited because of the rigidity of the surrounding structures (cricoid and thyroid cartilages), and the curvature of the tracheostomy tube at this level may obstruct the airway because of posterior membrane impingement [39]. Prior laryngotracheal injury, as with prolonged translaryngeal intubation, is a major risk factor for the development of subglottic stenosis after cricothyrotomy [31].

The association of cricothyrotomy with these possible complications leads most authorities to consider replacing a cricothyrotomy within 48 to 72 hours with a standard tracheostomy procedure. This is commonly done by an open surgical tracheostomy (OST), which occurs between the second and third tracheal rings, as compared to a percutaneous dilational tracheostomy (PDT), which usually occurs between the cricoid cartilage and the first ring or the first and second rings [39].
TRACHEOSTOMY PROCEDURES IN THE INTENSIVE CARE UNIT

Tracheostomy is one of the most common surgical ICU procedures and is commonly performed for weaning from mechanical ventilation; clearance of secretions; and airway protection for patients requiring prolonged ventilation. There are two major techniques for tracheostomy, open and percutaneous, with various modifications of each. The different surgical tracheostomy techniques are well described in the references for this chapter [3,40].

Open Surgical Tracheostomy

In OST, the patient’s neck is extended, and the surgical field is exposed from the chin to several inches below the clavicle. This area is prepped and draped, and prophylactic antibiotics are administered at the discretion of the surgeon. A vertical or horizontal incision may be used; however, a horizontal incision will provide a better cosmetic result. The platysma muscle is divided in line with the incision, and the strap muscles are separated in the midline. The thyroid isthmus is then mobilized superiorly or divided as needed to access the trachea. In the event of a low-lying cricoid cartilage, dissection on the anterior wall of the trachea helps to mobilize the trachea out of the mediastinum, and also the use of a cricoid hook will elevate the trachea to expose the second or third tracheal ring. Following identification of the second or third tracheal ring, a vertical tracheostomy is created, or a tracheal flap (Bjork flap) is fashioned to create a fistulous tract by suturing the tracheal mucosal flap to the skin in the incision.

Variations on this technique include the use of retention sutures through the lateral aspect of the tracheal walls for retraction purposes during tracheostomy tube insertion and for expeditious reinsertion of a tracheostomy tube in the event of accidental tube decannulation [40]. The tracheal “stoma” will, in most cases, mature after 7 to 10 days and will form a tract that will facilitate tube exchange or downsizing, thereby minimizing the risk of tube misplacement.

Percutaneous Dilational Techniques

The PDT are divided into several techniques; however, all are alike in that they depend on the basic technique of guidewire placement through the anterior tracheal wall, followed by dilation over this guidewire to create a
tracheal stoma. The procedure is performed with monitoring of $O_2$ saturation, cardiac rhythm, and blood pressure. Successful cannulation of the trachea may be verified with ETCO$_2$ monitoring. There are several different modifications from the original technique that was described by Ciaglia et al. [41] in 1988. These modifications are described in detail elsewhere [3].

Both techniques, PDT and OST, can be performed in either the ICU or the operating room. There have been several meta-analyses comparing OST with PDT, most showing no significant difference in mortality or major complications between the two methods of performing the tracheostomy. Freeman et al. [42] reviewed multiple prospective controlled studies published between 1991 and 1999 totaling 236 patients and concluded that there is no difference in mortality between PDT and OST, and that PDT was associated with less bleeding and stomal infections and was performed more rapidly. Delaney et al. [43] reported that there was no significant difference in mortality and major complications between PDT and OST in a meta-analysis consisting of 17 randomized trials and a total of 1,212 patients. They also showed a decrease in stomal infections in the PDT group, but no difference in bleeding complications. Similar findings were demonstrated by meta-analysis studies by Higgins and Punthakee [44] and Oliver et al. [45]. However, Dulguerov et al. [46] reviewed 3,512 patients from 48 studies performed between 1960 and 1996 and concluded that OST was more favorable than PDT. Subsequent critiques of these papers indicate the inherent weakness of heterogeneous patient populations, and the use of case series and nonrandomized studies in meta-analyses [47–49]. It is likely that experience and technical modifications allow both the techniques to be performed in appropriate patients with the same degree of safety and efficiency (<1% procedure-related mortality) [50].

Other factors have been used to justify the use of one procedure over the other such as cost efficiency [51]; bleeding; infection; procedural time; and estimated time from the decision to proceed to successful completion of the procedure [50]. Each factor can be used to justify one procedure over another, but it is likely that institutional practice variations and operator experience are more important in the selection of one procedure over another. This is particularly relevant with respect to the target population where ICU daily expenses far outweigh the procedural costs of either technique [52], and the expected patient mortality can be as high as 35% [53].

It is probably more important to judiciously use the institutional resources and the operator experience in providing the “best” tracheal technique for these compromised patients. It is possible that the target population may vary from one institution to another (cardiac vs. trauma vs. neurosurgical vs. medical ICU patients), which may influence the
decision to perform one technique over another. Patient body habitus also plays a large role in selection: difficulty palpating tracheal rings in a short, thick-necked patient makes percutaneous tracheostomy not only difficult but dangerous. This patient is better served in an operating room setting where optimum sedation/paralysis (if needed) and positioning can be accomplished while directly exposing the anterior trachea, mobilizing it if necessary to access the airway with an appropriately sized, sometimes custom-made, tube.

Nonetheless, there are certain distinct advantages of PDT that can be outlined as follows: (a) easier access for timing of the procedure; (b) reduced operating room and person power utilization; (c) PDT is less expensive than OST (even if both the procedures are performed in the ICU); (d) PDT has no requirement for transportation of critically ill patients to an operating room; (e) improved cosmetic results; and (f) possibly reduced rates of stomal infection, bleeding, and reduced tracheal secretions in the parastomal area owing to the tight fitting of the stoma around the tracheostomy tube.

We do recommend considering performing OST instead of PST in the following patients: (a) patients with severe respiratory failure (FiO₂ > 0.60, PEEP > 10, and complicated translaryngeal intubation or a nonpalpable cricoid cartilage or a cricoid cartilage <3 cm above the sternal notch [51]); (b) obese patients with abundant pretracheal subcutaneous fat; (c) patients with large goiters; (d) abnormal airways secondary to congenital or acquired conditions; (e) the need for constant attendance of a second physician to monitor ventilation or circulatory abnormalities; (f) abnormal bleeding diathesis that cannot be adequately corrected [54].

Utility of Ultrasonography for Percutaneous Tracheostomy

Ultrasonography has several useful applications related to PDT.

Identification of Aberrant Vascular Anatomy. A small proportion of patients have aberrant vascular anatomy that contraindicates PDT. Preprocedure ultrasonography examination of the anterior neck can identify dangerous vascular anatomy that precludes PDT [55–59]. The high frequency vascular transducer is used to obtain a transverse axis image of the anterior neck. Starting at the thyroid cartilage, the operator
moves the probe down the anterior neck in order to identify anomalous midline vascular structures that would preclude bedside PDT (Chapter 9 Videos 9.1 and 9.2). Once at the suprasternal notch, the probe is angled downward to examine for any high riding mediastinal artery or vein. The examination takes a few minutes, and is an effective means of improving the safety of the procedure.

Aberrant position of the carotid, brachiocephalic, right subclavian, or thyroid artery, or aortic arch, though rare, has been associated with severe hemorrhage during PDT (Chapter 9 Video 9.2). Large midline veins are also an occasional finding that contraindicates PDT (Chapter 9 Video 9.2). If and when dangerous vascular anatomy has been identified, this situation requires that the procedure be performed with standard open surgical technique in the operating room.

**Selection of Insertion Site.** While examining for vascular structures, the operator identifies the thyroid cartilage, the cricoid membrane, and the prominent cricoid cartilage below which are the tracheal rings. The insertion site is targeted to be below the first tracheal ring (Chapter 9 Video 9.1). Ultrasonography is particularly useful for selection of insertion site when physical examination is challenging such as with obesity or in the elderly patient with a low position of the cricoid cartilage. Once a safe site is identified, the operator may mark it for subsequent needle insertion, or proceed with real-time guidance of needle insertion using ultrasonography.

**Guidance of Needle Insertion.** Real-time ultrasonography guidance of needle insertion into the trachea may be performed during PDT [60]. It improves first pass success rate and accuracy of needle insertion when compared to standard technique [61]. Should the operator choose the option of real-time guidance, the probe is held in the transverse axis, and the needle is inserted into the trachea while tracking its movement with ultrasonography. Some operators insert the needle before making the skin incision. Alternatively, the skin incision is made first, with subsequent needle insertion under ultrasonography control.
TUBES AND CANNULAS

Characteristics of a good tracheostomy tube are flexibility to accommodate varying patient anatomies; inert material; wide internal diameter; the smallest external diameter possible; a smooth surface to allow easy insertion and removal; and sufficient length to be secured once placed, but not so long as to impinge the carina or other tracheal parts. Until the late 1960s, when surgeons began to experiment with silicone and other synthetic materials, tracheostomy tubes and cannulas were made of metal. At present, almost all tracheostomy tubes are made of synthetic materials. One disadvantage of a silicone tube over a metal one is the increased thickness of the tube wall, resulting in a larger outer diameter. Silicone tubes are available with or without a cuff. The cuff allows occlusion of the airway around the tube, which is necessary for positive-pressure ventilation. It may also minimize aspiration. In the past, cuffs were associated with a high incidence of tracheal stenosis caused by ischemia and necrosis of the mucus membrane and subsequent cicatricial contracture at the cuff site. High-volume, low-pressure cuffs diminish pressure on the wall of the trachea, thereby minimizing (but not eliminating) problems caused by focal areas of pressure necrosis [62]. Cuff pressures should be maintained at 15 to 20 cm H₂O, because higher pressures impair mucosal capillary blood flow leading to ischemic injury to the trachea [63]. Cuff pressures should be checked with a manometer daily in critically ill patients. Once the patient is weaned from mechanical ventilation, the cuff should be deflated, or consideration should be given to placing an uncuffed tracheostomy tube until the patient can be decannulated. When the only purpose of the tube is to secure the airway (sleep apnea) or provide access for suctioning secretions, a tube without a cuff can be placed. A comprehensive review of tracheostomy tubes can be found elsewhere [64].
The care of a tracheostomy tube is important. Highlighted below are some specific issues that all intensivists need to know when caring for patients with tracheostomies.

Wound and Dressing Care

Daily examinations of the stoma are important in identifying infections or excoriations of the skin at the tracheostomy site [65]. In addition, keeping the wound clean and free of blood and secretions is important, especially in the immediate posttracheostomy period. Dressing changes should be performed at least twice a day and when the dressings are soiled. Some authors recommend cleaning the stoma with a 1:1 mixture of hydrogen peroxide and sterile saline [65]. When changing dressings and tapes, special care is needed to avoid accidental dislodging of the tracheostomy tube. Sutures, placed either for fixation and/or through the rings themselves for exposure, should be removed as soon as practical, usually after 1 week when an adequate stoma has formed, to facilitate cleaning the stomal area. Malodorous tracheal “stomatitis” that can lead to an enlarging stoma around the tube should be treated with topical antimicrobial dressings such as 0.25% Dakin’s solution to facilitate resolution. Significant induration and/or cellulitis should be managed with a systemic antibiotic such as clindamycin. Occasionally, the secretions become extremely malordorous, indicating a gram-negative or anaerobic infection or overgrowth: this should be treated with topical and systemic antimicrobials.

Inner Cannulas

The inner cannulas should be used at all times in most tracheostomy tubes in the ICU. Bivona makes a tracheostomy tube that is lined with silicone and does not require an inner cannula. In other tracheotomy tubes, inner cannulas serve to extend the life of the tracheostomy tubes by preventing the buildup of secretions within the tracheostomy. The inner cannulas can be easily removed and either cleaned or replaced with a sterile, disposable one. Disposable inner cannulas have the advantage of quick and efficient changing; a decrease in nursing time; decreased risk of cross-contamination; and guaranteed sterility. The obturator should be
kept at the bedside at all times in the event that reinsertion of the tracheostomy is necessary.

Humidification
One of the functions of the upper airway is to moisten and humidify inspired air. Because tracheostomies bypass the upper airway, it is vital to provide patients who have tracheostomies with warm, humidified air. Humidification of inspired gases prevents complications in patients with tracheostomies. Failure to humidify the inspired gases can result in obstruction of the tube by inspissated secretions, impaired mucociliary clearance, and decreased cough.

Suctioning
Patients with tracheostomies frequently have increased amounts of airway secretions coupled with decreased ability to clear them effectively. Keeping the airways clear of excess secretions is important for decreasing the risk of lung infection and airway plugging [65]. Suctioning is frequently required in patients with poor or ineffective cough. Suction techniques should remove the maximal amount of secretions while causing the least amount of airway trauma. Routine suctioning, however, is not recommended [66]. In the patient who requires frequent suctioning because of secretions, who otherwise appears well, without infection and without tracheitis, the tube itself may be the culprit. Downsizing the tube or even a short trial (while being monitored) with the tube removed may result in significantly less secretions, obviating the need for the tube.

Tracheostomy Tube Changes
Tracheostomy tubes do not require routine changing. In fact, there may be significant risks associated with routine tracheostomy tube changes, especially if this is performed within a week of the initial procedure and by inexperienced caregivers. A survey of accredited otolaryngology training programs suggested a significant incidence of loss of airway and deaths associated with routine changing of tracheostomy tubes within 7 days of initial placement, especially if they are changed by inexperienced physicians [67]. In general, the tube needs to be changed only under the following conditions: (a) there is a functional problem with it, such as an air leak in the balloon; (b) when the lumen is narrowed because of the buildup of dried secretions; (c) when switching to a new type of tube; or (d) when downsizing the tube prior to decannulation. Ideally, a tracheostomy tube should not be changed until 7 to 10 days after its initial placement. The reason for this is to allow the tracheal stoma and
the tract to mature. Patients who have their tracheostomy tube changed before the tract is fully mature risk having the tube misplaced into the soft tissue of the neck. If the tracheostomy tube needs to be replaced before the tract has had time to mature, the tube should be changed over a guide, such as a suction catheter or tube changer with personnel and equipment readily available at the bedside to perform orotracheal intubation if needed.

**Oral Feeding and Swallowing Dysfunction Associated with Tracheostomies**

Caution should be exercised before initiating feedings by mouth in patients with tracheostomy, because numerous studies have demonstrated that patients are at a significantly increased risk for aspiration when a tracheostomy is in place. Physiologically, patients with tracheostomies are more likely to aspirate because the tracheostomy tube tethers the larynx, preventing its normal upward movement needed to assist in glottic closure and cricopharyngeal relaxation. Tracheostomy tubes also disrupt normal swallowing by compressing the esophagus and interfering with deglutition, decreasing duration of vocal cord closure and resulting in uncoordinated laryngeal closure [68,69]. In addition, prolonged translaryngeal intubation can result in swallowing disorders that persist even after the endotracheal tube is converted to a tracheostomy [70]. It is therefore not surprising that between 40% and 65% of patients with tracheostomies aspirate when swallowing [71]. It is felt that between 73% and 77% of the episodes are clinically silent [71].

Before attempting oral feedings in a patient with a tracheostomy, several objective criteria must be met. The patient must be consistently alert, and able to follow complex commands. The patient should have adequate cough and swallowing reflexes; adequate oral motor strength; and a significant respiratory reserve. These criteria are probably best assessed by a certified speech therapist. However, bedside clinical assessment may only identify 34% of the patients at high risk for aspiration [72]. Augmenting the bedside swallowing evaluation by coloring feedings or measuring the glucose in tracheal secretions does not appear to increase the sensitivity in detecting the risk of aspiration [73]. A video barium swallow may identify between 50% and 80% of patients with tracheostomies who are at a high risk to aspirate oral feeding [72]. A laryngoscopy to observe directly a patient’s swallowing mechanics, coupled with a video barium swallow, may be more sensitive in predicting which patients are at risk for aspiration [72]. Scintigraphic studies may be the most sensitive test for identifying aspiration [74]. Plugging of the tracheostomy [67] or using a Passy–Muir valve may reduce aspiration in patients with tracheostomies who are taking oral feedings, but this is not
a universal finding [75].

Because of the high risk for aspiration and the difficulty assessing which patients are at high risk to aspirate, we do not institute oral feedings in our patients with tracheostomy in the ICU. We believe that the potential risks of a percutaneous endoscopically placed gastrostomy feeding tube or maintaining a nasogastric feeding tube are much less than the risk of aspiration of oral feedings and its complications (i.e., recurrent pneumonia, acute respiratory distress syndrome, and prolonged weaning).

**Discharging Patients with Tracheotomies from the ICU to the General Ward**

Multiple studies have raised concern about the safety of patients who have been weaned from mechanical ventilation and who are transferred from the ICU to the general hospital ward with the tracheostomy in place [76,77]. Fernandez et al. retrospectively showed an increased mortality in patients with tracheostomy tubes versus those decannulated prior to transfer out of the ICU, especially among patients with a poorer overall prognosis [76]. Martinez et al. prospectively studied 73 patients who received tracheostomies, who were without neurologic injury, and who were transferred from the ICU to the general ward [77]. Thirty-five of these patients were decannulated prior to transfer to the wards. The decannulated group had a significantly lower mortality. Factors found to be associated with increased mortality in patients not decannulated prior to transfer include body mass index greater than 30 kg per m$^2$ and tenacious secretions.

Patients with tracheostomies who are transferred to the general medical wards need special attention. A multidisciplinary care model has been shown to significantly expediate the decannulation process while also reducing the complication rate in a small study in the UK [78]. We suggest that patients with tracheostomies can be safely cared for in the general ward, provided there is an interprofessional team approach between physicians, nurses, and respiratory therapists.
Tracheostomies, whether inserted by percutaneous dilatation or open surgical procedure, are associated with a variety of complications. These complications are best grouped by the time of occurrence after the placement and are divided into immediate, intermediate, and late complications (Table 9.4). The reported incidence of complications varies from 4% [79] to 39% [19], with reported mortality rates from 0.03% to 0.6% [46,80]. Complication rates decrease with increasing experience of the physician performing the procedure [81]. Posttracheostomy mortality and morbidity are usually caused by iatrogenic tracheal laceration, hemorrhage, tube dislodgment, infection, or obstruction [3]. Neurosurgical patients have a higher posttracheostomy complication rate than other patients [3]. Tracheostomy is more hazardous in children than in adults, and carries special risks in the very young, often related to the experience of the surgeon [82]. A comprehensive understanding of immediate, intermediate, and late complications of tracheostomy and their management is essential for the intensivist.

Multiple studies have suggested an increased complication rate of surgical tracheostomy in patients with a BMI > 30 [8,83]. There is conflicting evidence regarding the complication rate of percutaneous tracheostomy in these patients. Byhahn et al. found a complication rate of percutaneous tracheostomy of 43.8% in 32 patients with a BMI > 27, compared to 18.2% in 73 patients with a BMI < 27 (p < 0.001). Additionally, the rate of severe complication in the obese group was nearly five times that of those in the nonobese group [84]. However, a subsequent study by Romero et al. of 25 obese patients and 80 nonobese patients undergoing fiber-optic bronchoscopy-guided percutaneous tracheostomy with ultrasound support did not show any significant difference in complication rates (8% vs. 7.5%, p = 1) [85]. In the largest study to date, McCague et al. retrospectively reviewed 131 obese patients and 295 nonobese patients undergoing bronchoscopy-guided percutaneous tracheostomy and did not find a significant difference in complication rate [86]. Overall, these studies are limited by the small numbers; retrospective or observational nature; and lack of long-term follow-up.

**Obstruction**

Obstruction of the tracheostomy tube is a potentially life-threatening complication. The tube may become plugged with clotted blood or inspissated secretions. In this case, the inner cannula should be removed immediately and the patient suctioned. Should that fail, it may be necessary to remove the outer cannula also, a decision that must take into consideration the reason the tube was placed and the length of time it has been in place. Obstruction may also be caused by angulation of the distal end of the tube against the anterior or posterior tracheal wall. An
undivided thyroid isthmus pressing against the angled tracheostomy tube can force the tip against the anterior tracheal wall, whereas a low superior transverse skin edge can force the tip of the tracheostomy tube against the posterior tracheal wall. An indication of this type of obstruction is an expiratory wheeze. Division of the thyroid isthmus, and proper placement of transverse skin incisions prevent anterior or posterior tube angulation and obstruction.

**Tube Displacement/Dislodgment**

Dislodgment of a tracheostomy tube that has been in place for 2 weeks or longer is managed by replacing the tube. If it cannot be immediately replaced or if it is replaced and the patient cannot be ventilated (indicating that the tube is not in the trachea), orotracheal intubation should be performed. Immediate postoperative displacement can be fatal, if the tube cannot be promptly replaced and the patient cannot be reintubated.

Dislodgment in the early postoperative period is usually caused by one of several technical problems. Failure to divide the thyroid isthmus may permit the intact isthmus to ride up against the tracheostomy tube and thus displace it. Excessively low placement of the stoma (i.e., below the second and third rings) can occur when the thoracic trachea is brought into the neck by overextending the neck or by excessive traction on the trachea. When the normal anatomic relationships are restored, the trachea recedes below the suprasternal notch, causing the tube to be dislodged from the trachea. The risk of dislodgment of the tracheostomy tube, a potentially lethal complication, can be minimized by (a) transection of the thyroid isthmus at surgery, if indicated; (b) proper placement of the stoma; (c) avoidance of excessive neck hyperextension and/or tracheal traction; (d) application of sufficiently tight tracheostomy tube retention tapes; (e) suture of the tracheostomy tube flange to the skin in patients with short necks; and (f) insertion of a tracheostomy tube of an appropriate length for the patient’s anatomy. Some surgeons apply retaining sutures to the trachea for use in the early postoperative period in case the tube becomes dislodged, allowing the trachea to be pulled into the wound for reintubation. Making a Bjork flap involves suturing the inferior edge of the trachea stoma to the skin, thus allowing a sure pathway for tube placement. Bjork flaps, however, tend to interfere with swallowing and promote aspiration. Reintubation of a tracheostomy can be accomplished by using a smaller, beveled endotracheal tube and then applying a tracheostomy tube over the smaller tube, using the Seldinger technique [87].
If a tracheostomy becomes dislodged within 7 to 10 days of surgery, we recommend translaryngeal endotracheal intubation to establish a safe airway. The tracheostomy tube can then be replaced under less urgent conditions, with fiber-optic guidance if needed.

**Subcutaneous Emphysema**

Approximately 5% of patients develop subcutaneous emphysema after tracheostomy [87]. It is most likely to occur when dissection is extensive and/or the wound is closed tightly. Partial closure of the skin wound is appropriate, but the underlying tissues should be allowed to approximate naturally. Subcutaneous emphysema generally resolves over the 48 hours after tracheostomy, but when the wound is closed tightly and the patient is coughing or on positive-pressure ventilation, pneumomediastinum, pneumopericardium, and/or tension pneumothorax may occur [3].

**Pneumothorax and Pneumomediastinum**

The cupola of the pleura extends well into the neck, especially in patients with emphysema; thus, the pleura can be damaged during tracheostomy. This complication is more common in the pediatric age group because the pleural dome extends more cephalad in children. The incidence of pneumothorax after tracheostomy ranges from 0% to 5% [79,87]. Many surgeons routinely obtain a postoperative chest radiograph.

**Hemorrhage**

Minor postoperative fresh tracheostomy bleeding occurs in approximately 12.5% of cases and is the most common complication of this procedure [88]. Postoperative coughing and straining can cause venous bleeding by dislodging a clot or ligature. Elevating the head of the bed, packing the wound, and/or using homeostatic materials usually controls minor bleeding. Major bleeding can occur in up to 5% of tracheotomies and is caused by hemorrhage from the isthmus of the thyroid gland; loss of a ligature from one of the anterior jugular veins; or injury to the transverse jugular vein that crosses the midline just above the jugular notch. Persistent bleeding may require a return to the operating room for management. Techniques to decrease the likelihood of early posttracheostomy hemorrhage include (a) use of a vertical incision; (b) careful dissection in the midline, with care to pick up each layer of tissue with instruments rather than simply spread tissues apart; (c) liberal use of ligatures rather than electrocautery; and (d) careful division and suture ligation of the thyroid isthmus. Late hemorrhage after
tracheostomy is usually because of bleeding granulation tissue or another relatively minor cause. However, in these late cases, a tracheoinnominate artery fistula needs to be ruled out.

**Tracheoinnominate Artery Fistula**

At one point, it had been reported that 50% of all tracheostomy bleeding occurring more than 48 hours after the procedure was because of an often fatal complication of rupture of the innominate artery caused by erosion of the tracheostomy tube at its tip or cuff into the vessel [87]. However, because of the advent of the low-pressure cuff, the incidence of this complication has decreased considerably and occurs less than 1% of the time [89].

Eighty-five percent of tracheoinnominate fistulas occur within the first month after tracheostomy [90], although they have been reported as late as 7 months after operation. Other sites of delayed exsanguinating posttracheostomy hemorrhage include the common carotid artery; superior and inferior thyroid arteries; aortic arch; and innominate vein [90]. Rupture and fistula formation are caused by erosion through the trachea into the artery because of excessive cuff pressure or by angulation of the tube tip against the anterior trachea. Infection and other factors that weaken local tissues, such as malnourishment and steroids, also seem to play a role [91]. The innominate artery rises to about the level of the sixth ring anterior to the trachea, and low placement of the stoma can also create close proximity of the tube tip or cuff to the innominate artery. Rarely, an anomaly of the innominate, occurring with an incidence of 1% to 2% [90], is responsible for this disastrous complication. Pulsation of the tracheostomy tube is an indication of potentially fatal positioning [90]. Initially, hemorrhage from a tracheoinnominate fistula is usually not exsanguinating. Herald bleeds must be investigated promptly using fiber-optic tracheoscopy. If a tracheoinnominate fistula seems probable (minimal tracheitis and anterior pulsating erosions), the patient should be taken to the operating room for evaluation. Historically, definitive management involves resection of the artery. However, there are several reported cases of successful treatment with endovascular stenting of the innominate artery [92,93]. The mortality rate approaches 100%, even with emergent surgical intervention [3]. Sudden exsanguinating hemorrhage may be managed by hyperinflation of the tracheostomy cuff tube or reintubation with an endotracheal tube through the stoma, attempting to place the cuff at the level of the fistula. A lower neck incision with blind digital compression on the artery may be part of a critical resuscitative effort. If a tracheoinnominate artery fistula is suspected, the patient should be evaluated in the operating room and preparations should be made for a possible sternotomy.
Misplacement of Tube

Misplacement of the tube can occur at the time of surgery or when the tube is changed or replaced through a fresh stoma. If not recognized, associated mediastinal emphysema and tension pneumothorax can occur, along with alveolar hypoventilation. Injury to neurovascular structures, including the recurrent laryngeal nerve, is possible [3]. The patient must be orally intubated or the tracheostoma recannulated. Some advise placing retaining sutures in the trachea at the time of surgery. The availability of a tracheostomy set at the bedside after tracheostomy facilitates emergency reintubation.

Tracheal Cartilage Fracture

Tracheal ring fracture is a common, though likely unrecognized, complication, with a rate of 9.6% in one series of 219 percutaneous tracheostomy procedures [94]. These fractures likely are associated with the development of stenosis over time. Many preventative techniques have been suggested, including assuring bronchoscopic confirmation of placement; avoiding rotational torque at insertion site; perpendicular insertion; application of counterforce to the anterior tracheal wall with the endotracheal tube/bronchoscope; complete adequate skin incision and blunt soft tissue dissection to prevent excessive force on insertion; ensuring proper fit between tracheostomy and obturator; the use of tapered tracheostomies; and the smallest tracheostomy required by the patient.

Stomal Infections

A less than 2% incidence of local infection rate has been reported with tracheostomy [8]. The risk of serious infection is less than 0.5% [79]. Attention to the details of good stoma care and early use of antibiotics are advised. However, prophylactic antibiotics are not recommended [95].

Tracheoesophageal Fistula

Tracheoesophageal fistula caused by injury to the posterior tracheal wall and cervical esophagus occurs in less than 1% of patients, more commonly in the pediatric age group. Early postoperative fistula is a result of iatrogenic injury during the procedure [87]. The chances of creating a fistula can be minimized by entering the trachea initially with a
horizontal incision between two tracheal rings (the second and third), thereby eliminating the initial cut into a hard cartilaginous ring [3]. A late tracheoesophageal fistula may be because of tracheal necrosis caused by tube movement or angulation, as in neck hyperflexion, or excessive cuff pressure [87]. A tracheoesophageal fistula should be suspected in patients with cuff leaks, abdominal distention, recurrent aspiration pneumonia, and reflux of gastric fluids through the tracheostomy site. It may be demonstrated on endoscopy and contrast studies. Tracheoesophageal fistulas require surgical repair. For patients who could not tolerate a major surgical procedure, placement of an esophageal and a tracheal stent may be used [96].

Tracheal Stenosis

Some degree of tracheal stenosis is seen in 40% to 60% of patients following tracheostomy [80,97]. However, only 3% to 12% of these stenoses are clinically significant enough to require intervention [98]. Stenosis most commonly occurs at the level of the stoma or just above the stoma, but distal to the vocal cords [3]. The stenosis typically results from bacterial infection or chondritis of the anterior and lateral tracheal walls. Granulation tissue usually develops first. Ultimately, the granulation tissue matures, becoming fibrous and covered with a layer of epithelium. The granulation tissue itself can also result in other complications, such as obstructing the airway at the level of the stoma, making changing the tracheostomy tube difficult, and occluding tube fenestrations. Identified risk factors for developing tracheal stenosis include sepsis; stomal infections; hypotension; advanced age; male gender; corticosteroid use; excess motion of the tracheostomy tube; oversized tube; prolonged placement; elevated cuff pressures; excessive excision of the anterior tracheal cartilage; and fracturing a tracheal ring during PDT [99]. Using properly sized tracheostomy tubes, inflating cuffs only when indicated, and maintaining intracuff pressures to less than 15 to 20 mm Hg may decrease the incidence of tracheal stenosis [100]. Tracheal stenosis, as well as other long-term complications, appears to be less frequent with the percutaneous procedure [101,102].

Treatment options for granulation tissue include topical strategies (such as topical antibiotic or steroids, silver nitrate, and polyurethane form dressings) or surgical strategies (laser excision, electrocautery, and surgical removal) [3]. Treatment options for symptomatic tracheal stenosis include dilatation with a rigid bronchoscopy with coring, intralumen laser excision, or surgical resection with end-to-end tracheal anastomosis.

Tracheomalacia
Tracheomalacia is a weakening of the tracheal wall resulting from ischemic injury to the trachea, followed by chondritis, then destruction, and necrosis of the tracheal cartilage. Consequently, there is collapse of the affected portion of the trachea with expiration, resulting in airflow limitation, air trapping, and retention of airway secretions. Tracheomalacia may ultimately result in the patient failing to wean from mechanical ventilation. A short-term therapeutic approach to tracheomalacia is to place a longer tracheostomy tube to bypass the area of malacia. Long-term treatment options include stenting, tracheal resection, or tracheoplasty.

**Dysphagia and Aspiration**

The major swallowing disorder associated with tracheostomy is aspiration (see the section Oral Feeding and Swallowing Dysfunction Associated with Tracheostomies). Because of the high risk for aspiration, we do not recommend oral feeding in ICU patients with tracheostomies.

**Tracheocutaneous Fistula**

Although the tracheostoma generally closes rapidly after decannulation, a persistent fistula may occasionally remain, particularly when the tracheostomy tube is present for a prolonged period. If this complication occurs, the fistula tract can be excised and the wound closed primarily under local anesthesia. More complicated or persistent fistulas required a more formal procedure under general anesthesia involving the use of a local muscle flap between the tracheal opening and the subcutaneous tissues.
CONCLUSIONS

Tracheostomy is one of the most common surgical procedures performed in the ICU and appears to be the airway of choice for patients requiring mechanical ventilation for more than 10 to 14 days. In the majority of patients, there is unlikely a benefit to tracheostomy prior to 7 to 10 days of mechanical ventilation. The physician performing the tracheostomy procedure needs to assess each patient to determine the best technique (whether it be performed bedside percutaneously or open in the operating room) for that specific patient. The patient’s medical condition; the physician’s experience with the various techniques; and the hospital’s resources all need to be considered in determining the type of procedure performed.
REFERENCES

---

Flexible bronchoscopy (FB) was first introduced in 1968 by Dr. Shigeto Ikeda, the Japanese physician, who is regarded as the “father” of FB. Since then, further technological advances have facilitated its widespread utilization and it has evolved into an invaluable tool for diagnosis and therapy of a wide variety of respiratory diseases in the intensive care unit (ICU) [1]. Because of its safety and low complication rate [2], FB has largely replaced rigid bronchoscopy as the procedure of choice for most endoscopic evaluations of the airway and lung parenchyma. However, rigid bronchoscopy still plays a potential and pivotal role in the evaluation and management of (a) brisk, massive hemoptysis, defined broadly as 200 to 600 mL per 24 hours; (b) extraction of foreign bodies; (c) endobronchial resection of granulation tissue that can occur after traumatic and/or prolonged intubation; (d) biopsy of potentially vascular tumors (e.g., bronchial carcinoid), in which brisk and excessive bleeding can be controlled by packing and enhanced suction capabilities; (e) endoscopic-mechanical and laser-based debridement/destruction of airway tumors; and (f) dilation of tracheobronchial strictures and management of extrinsic airway constriction via placement of airway stents. In the last three decades, there has been renewed interest in the use of rigid bronchoscopy by pulmonologists, driven by the advent of dedicated endobronchial prostheses (airway stents) in the early 1990s for the management of both malignant and benign central airway obstruction [3,4]. These advances have fueled the growth of the established field of interventional pulmonology (IP); comprehensive guidelines have been published in the last decade by the American College of Chest Physicians and European Respiratory Society [3,5]. In this chapter, we discuss primarily the role of FB in the ICU but the reader is referred to Chapter 182 for the role of IP in the ICU.
GENERAL CONSIDERATIONS

Because FB can be performed easily even in intubated patients, the same general indications apply to critically ill patients on ventilators and non-critically ill patients; however, only the diagnostic and therapeutic indications most commonly encountered in the ICU are discussed here. Where relevant, the potential application of advanced bronchoscopic diagnostic and therapeutic interventions in the ICU setting are also discussed.
COMMON DIAGNOSTIC INDICATIONS

Hemoptysis

Hemoptysis is one of the most common clinical problems for which bronchoscopy is indicated [6]. Whether the patient complains of blood streaking or massive hemoptysis, bronchoscopy should be considered to localize/lateralize the site of bleeding and possibly diagnose the cause. Localization of the site of bleeding is crucial if temporizing or definitive therapy, such as surgery, becomes necessary, and it is also useful to guide angiographic procedures (bronchial or pulmonary artery embolization). Whenever patients have an endotracheal or tracheostomy tube in place, hemoptysis should always be evaluated, because it may indicate potentially life-threatening tracheal injury. Unless the bleeding is massive, a flexible bronchoscope, rather than a rigid bronchoscope, is the initial instrument of choice for evaluating hemoptysis. In the setting of massive hemoptysis, however, the patient is at risk of imminent decompensation and death due to asphyxiation. Stabilization of the patient, focusing on establishing a secure airway, and timely communication with pulmonology/IP, thoracic surgery, anesthesiology, and interventional radiology is of utmost importance. This coordinated, interprofessional effort should focus on rapid transfer to the operation room suite for rigid bronchoscopy. The rigid bronchoscope is ideal in this situation because it provides a secure route for ventilation, serves as a larger conduit for adequate suctioning, and can quickly isolate the lung in the case of a lateralized bleeding source. In most situations, once an adequate airway has been established and initial suctioning of excessive blood has been performed, the flexible bronchoscope can be used as a complementary modality inserted through the rigid bronchoscope to more accurately assess, localize, and temporize the source of bleeding within and beyond the main bronchi [7].

Diffuse Parenchymal Disease

The clinical setting influences the choice of procedure. When diffuse pulmonary infiltrates suggest sarcoidosis, lymphangitic carcinomatosis, or eosinophilic pneumonia, for example, transbronchial lung biopsy (TBLB) should be considered initially because it has an extremely high yield in these situations. However, TBLB has a low yield for the definitive
diagnosis of most idiopathic interstitial pneumonias, inorganic pneumoconiosis, and pulmonary vasculitides \[8\]; when these disorders are suspected, surgical lung biopsy is the gold standard and procedure of choice. Although TBLB is usually not adequate for histologic diagnosis of pulmonary fibrosis and acute interstitial pneumonia, it may provide sufficient information to guide therapy in a critically ill patient by excluding infection.

**Ventilator-Associated Pneumonia**

The ability to determine the probability of ventilator-associated pneumonia (VAP) is very limited, with a sensitivity of only 50% and a specificity of 58% \[9\]. Quantitative cultures obtained via bronchoscopy may thus play an important role in the diagnostic strategy. Quantitative cultures of bronchoalveolar lavage (BAL) fluid and protected specimen brush (PSB), with thresholds of \(10^4\) colony-forming units (CFU) per mL and \(10^3\) CFU per mL, respectively, are most commonly employed prior to initiation of antimicrobial therapy when a semi-invasive approach is taken. Cultures of bronchial washings do not add to the diagnostic yield of quantitative BAL culture alone \[10\]. For a brief description of how to perform BAL and obtain PSB cultures, see the “Procedure” section, given later in the chapter.

For BAL, an evidence-based analysis of 23 prior investigations yielded a sensitivity of 73% and a specificity of 82%, indicating that BAL cultures fail to diagnose VAP in almost one-fourth of all cases \[11\]. A similar analysis of PSB cultures indicates a very wide range of results, with a sensitivity of 33% to greater than 95% and a median of 67%, and a specificity of 50% to 100% with a median of 95% \[12\]. PSB is thus more specific than it is sensitive, and negative results may not be sufficient to exclude the presence of VAP. Blind protected telescoping catheter specimens yield similar results to bronchoscopically directed PSB and BAL cultures \[13\]. Despite the greater accuracy of quantitative bronchoscopic cultures, prospective randomized trials of early invasive diagnostic strategies employing bronchoscopy and quantitative lower respiratory tract cultures for VAP have not demonstrated significant advantages in mortality or other major clinical end points over simpler methods \[14\]. A Cochrane database review combining five such randomized controlled trials showed no improvement in mortality, duration of mechanical ventilation, or length of ICU stay \[15\]. On the basis of these findings, routine use of bronchoscopy over semiquantitative endotracheal suctioning cultures in immunocompetent adults with suspected VAP cannot be recommended.

**Pulmonary Infiltrates in Immunocompromised Patients**
When an infectious process is suspected, the diagnostic yield depends on the organism and the immune status of the patient. Numerous recent investigations have examined the utility of bronchoscopy in immunocompromised patients. Most of these investigations have found that the diagnostic yield of BAL in such patients is approximately 50% and that the results of BAL lead to a change in treatment in 17% to 38% of patients. In one prospective multicenter trial [16], BAL was the only conclusive diagnostic study in 33% of patients. Although it is difficult to distinguish respiratory decompensation caused by bronchoscopy from the natural history of the patients’ underlying disease, the same study found that 48% of patients developed deterioration in respiratory status after bronchoscopy and 27% of patients were intubated. Because of these concerns, novel approaches to FB have been used in such patients including the utilization of noninvasive positive pressure ventilation or high flow nasal cannula during the procedure [17]. Transbronchial biopsy may add only a little to the diagnostic yield of BAL in immunocompromised patients, with an incremental yield of 7% to 12% [18]. In some series, the major complication rate of transbronchial biopsy was greater than the diagnostic utility, including a 14% incidence of major bleeding requiring intubation [18]. However, in AIDS patients, the sensitivity of lavage and/or TBLB for identifying all opportunistic organisms can be as high as 87% [19]. Transbronchial biopsy adds significantly to the diagnostic yield in AIDS patients and may be the sole means of making a diagnosis in up to 24% of patients, including diagnoses of *Pneumocystis jirovecii*, *Cryptococcus neoformans*, *Mycobacterium tuberculosis*, and occasionally nonspecific interstitial pneumonitis [20]. Lavage alone may have a sensitivity of up to 97% for the diagnosis of *P. jirovecii* pneumonia [21]. However, because induced sputum samples can also be positive for *P. jirovecii* in up to 79% of cases [21], induced expectorated sputum, when available, should be evaluated first for this organism before resorting to bronchoscopy. More recently, the use of serum-based markers such as β-2 glucan and galactomannan have also been used in certain settings to guide diagnosis and therapy [22] when *P. jirovecii* and aspergillus infections are considered.

**Acute Inhalation Injury**

In patients suffering from smoke inhalation, flexible nasopharyngoscopy, laryngoscopy, and bronchoscopy are indicated to identify the anatomic level and severity of injury. Prophylactic intubation should be considered if considerable upper airway mucosal injury is noted early; acute respiratory failure is more likely in patients with mucosal changes seen at segmental or lower levels. Upper airway obstruction is a life-threatening problem that usually develops during the initial 24 hours after inhalation.
injury. It correlates significantly with increased size of cutaneous burns, burns of the face and neck, and rapid intravenous fluid administration, and also portends a greater mortality [23].

Blunt Chest Trauma

Patients may present with atelectasis, pulmonary contusion, hemothorax, pneumothorax, pneumomediastinum, or hemothorax. Prompt bronchoscopic evaluation of such patients has a diagnostic yield of 53%; findings may include tracheal or bronchial laceration or transection (14%), aspirated material (6%), supraglottic tear with glottic obstruction (2%), mucus plugging (15%), and distal hemorrhage (13%) [24,25]. Many of these diagnoses may not be clinically evident and require surgical intervention.

Postresectional Surgery and Lung Transplantation

FB can identify a disrupted suture line causing bleeding and pneumothorax following surgery and an exposed endobronchial suture causing refractory cough. In these postpneumonectomy situations, the location of dehiscence and the subsequent bronchopleural fistula (BPF) can be identified visually via FB at the stump site. However, when the BPF occurs in the setting of acute respiratory distress syndrome (ARDS) or necrotizing pneumonia, localization at the segmental and subsegmental level (defects less than 2 to 5 mm in diameter) can be more challenging. FB also appears to be safe and effective in guiding clinical management in critically ill lung transplant recipients when considering infection or rejection [26].

Assessment of Intubation-Related Injury

When a nasotracheal or orotracheal tube of the proper size is in place, the balloon can be routinely deflated and the tube withdrawn over the bronchoscope to look for upper airway injury. The technique involves withdrawing the tube up through the vocal cords and over the flexible bronchoscope to assess glottic and supraglottic damage. This technique may be useful after reintubation for stridor, or when deflation of the endotracheal tube cuff does not produce a significant air leak, suggesting the potential for life-threatening upper airway obstruction when extubation takes place. The flexible bronchoscope may readily identify mechanical problems such as increased airway granulation tissue leading
to airway obstruction, tracheal tears, tracheal stenosis at pressure points along the artificial airway–tracheal interface, and tracheobronchomalacia.
THERAPEUTIC INDICATIONS

Atelectasis

Bronchoscopy has a success rate of up to 89% in cases of lobar atelectasis, but only produced clinical improvement in 44% of patients when performed for retained secretions [27]. Two randomized trials found no advantage of bronchoscopy over a very aggressive regimen of frequent chest physiotherapy, recruitment maneuvers, saline nebulization, and postural drainage [28,29]. These studies also found that the presence of air bronchograms on the initial chest X-ray predicted relative failure of either intervention to resolve the atelectasis. Occasionally, the direct instillation of N-acetylcysteine through the bronchoscope may be necessary to liquefy the thick, tenacious inspissated mucus [30]. Because N-acetylcysteine may induce bronchospasm in patients with asthma, these patients should be pretreated with a bronchodilator. In cases of complete lobar collapse, a bronchoscope with the largest suction/working channel diameter available (3 to 3.2 mm working channel) should be used.

Foreign Bodies

Although the rigid bronchoscope is considered by many to be the instrument of choice for removing foreign bodies, especially in the pediatric population, devices with which to grasp objects have been created and are available for use with the flexible bronchoscope. A recent systematic review of the adult literature showed that FB has a high success rate (92%) in removal of inhaled foreign bodies [31]. The success of FB for foreign body removal can be enhanced by rigorous preprocedure preparation, assuring the availability of appropriate ancillary grasping equipment, practicing a “dry run,” and ensuring that a bronchoscopist with experience in foreign body removal is involved. It is also important to have an appreciation for situations for which rigid bronchoscopy with added ancillary interventions, such as laser therapy or cryotherapy, might be useful (e.g., an embedded foreign body with significant granulation tissue reaction at risk of bleeding) [32].

Endotracheal Intubation

Intubation under endoscopic visualization may be planned in cases of a suspected difficult airway that cannot be easily intubated or properly ventilated using the flexible bronchoscope as an obturator for tube
passage [33]. This is also useful for the intubation of patients with central airway stents, as blind intubation carries the risk of stent migration and malpositioning of the endotracheal tube [34]. The bronchoscope of choice should be one with an outer diameter of 5.7 mm or more because thinner more flexible scopes lack the stiffness and enhanced maneuverability needed for successful intubation.

Hemoptysis

On rare occasions where brisk bleeding threatens asphyxiation, endobronchial tamponade may stabilize the patient before definitive therapy is performed. With the use of the flexible bronchoscope, usually passed through a rigid bronchoscope or endotracheal tube, a Fogarty catheter with balloon is passed into the bleeding lobar orifice. When the balloon is inflated and wedged tightly, the patient may be transferred to surgery or angiography for bronchial arteriography and bronchial artery embolization [35]. Other bronchial blocking and lung separation techniques have been described and reviewed in the literature [36]. The Arndt blocker is a dedicated bronchial blocker that has a wire loop at its distal end, which when looped around the distal end of the flexible bronchoscope, can be guided to the bleeding airway and inflated. Its position can be adjusted under direct visualization and it can be fixed to the outer proximal portion of the endotracheal tube. More simple techniques that take advantage of the flexible bronchoscope’s ability to act as a stylet for a single-lumen endotracheal tube can be used to isolate one lung. One can use the bronchoscope to preferentially intubate the right main or left main bronchus in an emergent situation. Hemostasis may also be achieved by using FB to apply oxidized regenerated cellulose mesh to the bleeding site, instill thrombin/thrombin–fibrinogen preparations, tranexamic acid and more traditionally, perform iced saline lavage or apply topical epinephrine (1:20,000) to decrease the bleeding [37]. In the case of a visibly bleeding endobronchial tumor, hemostasis can be attained with laser photocoagulation (Nd-YAG laser), electrocautery, or argon plasma coagulation.

Central Obstructing Airway Lesions

Some patients with cancer and others with benign lesions that obstruct the larynx, trachea, and major bronchi can be treated by electrocautery, laser photoablation, argon plasma coagulation, cryotherapy, or photodynamic therapy applied through the bronchoscope (rigid or flexible) [38,39]. FB can also be used to place catheters that facilitate endobronchial delivery of radiation (brachytherapy). Metallic or silicone endobronchial stents can be placed bronchoscopically to relieve stenosis of large central airways. Adequate insertion of stents and relief of stenosis
(especially due to extrinsic compression) is typically accompanied by dilation of the airway via rigid bronchoscopy or with balloon dilation applied with the aid of FB. Several issues regarding airway stents should be noted: silicone stents can only be placed via rigid bronchoscopy and metallic stents should generally not be used in the setting of a nonmalignant central airway obstruction because they are associated with excessive growth of granulation tissue with subsequent worsening of airway obstruction and can be very challenging to remove once this complication occurs [40]. The primary goal of the interventions described earlier for the management of malignant central airway obstruction is palliative. In many instances, these procedures also facilitate liberation from mechanical ventilation and liberation from the ICU [41]. It appears that for intubated ICU patients, FB performed at the bedside with stent deployment and resective interventions, when necessary, is just as effective as rigid bronchoscopic interventions in the appropriately selected patient [42].

Closure of Bronchopleural Fistula

After placement of a chest tube, drainage of the pleural space, and stabilization of the patient (e.g., infection and cardiovascular and respiratory systems), bronchoscopy can be used to visualize a proximal BPF or localize a distal BPF; it can also be used in attempts to close the BPF [43]. Please see Chapter 176 that comprehensively covers this topic.

Percutaneous Dilatational Tracheostomy

Flexible bronchoscopic guidance is extremely helpful during bedside percutaneous tracheostomy [44,45]. Please see Chapter 9 that comprehensively covers this topic.
COMPLICATIONS

When performed by a trained specialist, routine FB is extremely safe [2]. The rare deaths have been due to excessive premedication or topical anesthesia, respiratory arrest from hemorrhage, laryngospasm or bronchospasm, and cardiac arrest from acute myocardial infarction [46]. Nonfatal complications occurring within 24 hours of the procedure include fever that is usually cytokine mediated (1.2% to 24%), pneumonia (0.6% to 6%), vasovagal reactions (2.4%), laryngospasm or bronchospasm (0.1% to 0.4%), cardiac arrhythmias (0.9% to 4%), pneumothorax, anesthesia-related problems (0.1%), and aphonia (0.1%) [47]. Most investigations have found that the incidence of bacteremia after transoral FB is very low (0.7%) [48]. Current guidelines by the American Heart Association for respiratory tract procedures recommend prophylactic antibiotics only when incision or biopsy of the respiratory tract mucosa is anticipated. Prophylaxis is further restricted to patients with high-risk cardiac conditions (prosthetic valves, prior history of infective endocarditis, congenital heart disease, and cardiac transplantation with valvulopathy) only and no distinction is made between rigid bronchoscopy and FB [49].

Although routine bronchoscopy is extremely safe, critically ill patients appear to be at higher risk for complications. Patients with asthma are prone to develop laryngospasm and bronchospasm. Bone marrow and stem cell transplant recipients are more likely to develop major bleeding during bronchoscopy (0% to 14%) [50], particularly if PSB or TBLB is performed (7% to 14% vs. 1.5% for BAL alone). One investigation found that aspirin use did not increase bleeding risk after transbronchial biopsy [51]. However, a prospective cohort study showed that clopidogrel use greatly increases the risk of bleeding after TBLB and therefore should be discontinued 7 days before bronchoscopy with biopsies [52]. In critically ill, mechanically ventilated patients, bronchoscopy causes a transient decrease in PaO₂ (partial arterial oxygen pressure) of approximately 25% [53], and TBLB is more likely to result in pneumothorax (7% to 23%), particularly in patients with ARDS (up to 36%) [54].
CONTRAINDICATIONS

Bronchoscopy should not be performed (a) unless an experienced bronchoscopist is available; (b) when the patient will not or cannot cooperate; (c) when adequate oxygenation cannot be maintained during the procedure; (d) in unstable cardiac patients [55]; and (e) in untreated symptomatic patients with asthma [56]. British Thoracic Society (BTS) guidelines recommend a platelet count of at least 20,000 per μL for FB with BAL, but to liaison with the hematology team if TBLB is considered [1]. Other considerations include patients with uremia and lung transplantation, who are also at a higher risk of bleeding with TBLB [1]. In patients with recent cardiac ischemia, the major complication rate is low (3% to 5%) and is similar to that of other critically ill populations [57]. The major contraindications to rigid bronchoscopy include inability to tolerate general anesthesia, an unstable cervical spine, limited range of motion of the spine, any condition that inhibits opening of the jaw, and an inexperienced operator and staff [3].

Consideration of bronchoscopy in neurologic and neurosurgical patients requires attention to the effects of bronchoscopy on intracranial pressure (ICP) and cerebral perfusion pressure (CPP). In patients with head trauma, bronchoscopy causes the ICP to increase by at least 50% in 88% of patients and by at least 100% in 69% of patients despite the use of deep sedation and paralysis [58]. Because mean arterial pressure tends to rise in parallel with ICP, there is often no change in CPP. A recent retrospective cohort study showed no increase in neurologic or sedation-specific complications in patients with malignant space occupying brain lesions undergoing flexible or rigid bronchoscopy [59]. In such patients, the procedure should be accompanied by deep sedation, paralysis, and medications for cerebral protection for which thiopental and lidocaine should be considered. Cerebral hemodynamics should be continuously monitored to ensure that ICP and CPP are within acceptable levels in high-risk patients whenever possible. Caution is warranted in patients with markedly elevated baseline ICP or with borderline CPP.
PROCEDURE

For nonintubated patients, FB can be performed by the transnasal or transoral route with a bite block. There has also been a recent interest in performing noninvasive ventilation-assisted FB via face mask, first described in eight immunocompromised patients with infiltrates and severe hypoxemia (PaO₂/FiO₂ < 100) [60]. The procedure was well tolerated with either maintenance of or an improvement in oxygenation noted throughout, and none of the patients required intubation. Since then, multiple small randomized controlled trials using similar applications of noninvasive ventilation during bronchoscopy in expanded patient populations with severe hypoxemia (PaO₂/FiO₂ < 200) have been described with similar outcomes [61]. Thus, it appears that this technique, augmented by BAL, appears to be a safe, effective, and viable option for obtaining an early and accurate diagnosis of pneumonia in nonintubated, otherwise marginally stable, patients with severe hypoxemia. In intubated and mechanically ventilated patients, the flexible bronchoscope can be passed into the tube through a swivel adapter with a rubber diaphragm that will prevent loss of the delivered respiratory gases. To prevent dramatic increases in airway resistance and an unacceptable loss of tidal volume, the lumen of the endotracheal tube should be at least 2 mm larger than the outer diameter of the bronchoscope [62]. Thus, FB with an average adult-sized instrument (outside diameter of scope 4.8 to 5.9 mm) can be performed in a ventilated patient if there is an endotracheal tube in place that is 8 mm or larger in internal diameter. If the endotracheal tube is smaller, a pediatric bronchoscope (outside diameter 3.5 mm) or intubation endoscope (outside diameter 3.8 mm) must be used to prevent damage to the bronchoscope. Both diagnostic and therapeutic interventions via FB have also been performed more frequently in the last decade through laryngeal mask airways used to secure the airway in spontaneously breathing under general anesthesia [63].

Premedication

Topical anesthesia may be achieved using nebulized lidocaine with lidocaine jelly as a lubricant and by instilling approximately 3 mL of 1% or 2% lidocaine at the main carina and, if needed, into the lower airways.
Lidocaine is absorbed through the mucus membranes, producing peak serum concentrations that are nearly as high as that when the equivalent dose is administered intravenously, although toxicity is rare if the total dose does not exceed 6 to 7 mg per kg. In 2000, a study performed in otherwise healthy patients with asthma demonstrated the safety of topical lidocaine doses up to 8.2 mg per kg in this population [64] and subsequently led to this upper limit being recommended by the BTS in their guidelines for diagnostic FB [65]. A recent randomized control trial showed 1% lidocaine solution to be as effective as the 2% solution in achieving adequate topical anesthesia, at significantly lower cumulative doses [66]. In patients with hepatic or cardiac insufficiency, lidocaine clearance is reduced, and the dose should be decreased to a maximum of 4 to 5 mg per kg [67]. Administering nebulized lidocaine prior to the procedure substantially increases the total lidocaine dose without improving cough or patient comfort [68]. Moderate sedation with incremental doses of midazolam, titrated to produce light sleep, produces amnesia in more than 95% of patients, but adequate sedation may require a total of greater than 20 mg in some subjects [69]. Cough suppression is more effective when narcotics are added to benzodiazepine premedication regimens [70]. Premedication with intravenous anticholinergics has not been found to reduce secretions, decrease coughing, or prevent bradycardia, and has been associated with greater hemodynamic fluctuations when compared to placebo [71]. Propofol and fospropofol [72] have also been used with success during moderate sedation for bronchoscopy, and may have the advantage of more rapid onset and shorter recovery time. More recently, a double blinded prospective study showed that a sedative regimen of dexmedetomidine and propofol was associated with fewer episodes of desaturation when compared to remifentanil and propofol in patients undergoing FB, though it was associated with longer recovery times and slightly worse bronchoscopist satisfaction scores [73].

Mechanical Ventilation

Maintaining adequate oxygenation and ventilation while preventing breath stacking and positive end expiratory pressure (auto-PEEP) may be challenging when insertion of the bronchoscope reduces the effective lumen of the endotracheal tube by more than 50%. PEEP caused by standard scopes and tubes will approach 20 cm H₂O with the potential for volutrauma. The inspired oxygen concentration must be temporarily increased to 100% prior to starting the procedure. Expired volumes should be constantly monitored to ensure that they are adequate [62]. Meeting these ventilatory goals may require increasing the high-pressure limit in volume-cycled ventilation to near its maximal value, allowing the
ventilator to overcome the added resistance caused by the bronchoscope. Although this increases the measured peak airway pressure, the alveolar pressure is not likely to change significantly because the lung is protected by the resistance of the bronchoscope [62]. Alternatively, decreasing the inspiratory flow rate in an attempt to decrease measured peak pressures may paradoxically increase alveolar pressures by decreasing expiratory time and thus increasing auto-PEEP. Suctioning should be kept to a minimum and for short periods of time because it will decrease the tidal volumes being delivered and may lead to derecruitment and associated hypoxemia [74].

**Quantitative Cultures**

BAL is performed by advancing the bronchoscope until the tip wedges tightly in a distal bronchus in the area of greatest clinical interest. If the disease process is diffuse, perform the procedure in the right middle lobe because this is the area from which the largest returns are most consistently obtained. Three aliquots of saline, typically 35 to 50 mL, are then instilled and withdrawn; in some protocols, the first aliquot is discarded to prevent contamination with more proximal secretions. A total instilled volume of 100 mL with at least 5% to 10% retrieved constitutes an adequate specimen [75]. PSB may be performed through a bronchoscope by advancing the plugged catheter assembly until it projects from the bronchoscope. When the area of interest is reached (e.g., purulent secretions can be seen), the distal plug is ejected and the brush is then fully advanced beyond the protective sheath. After the specimen is obtained, the brush is pulled back into the sheath and only then is the catheter assembly removed from the bronchoscope.

Chapter 11

Lung Ultrasonography
PIERRE KORY • NAVITHA RAMESH • PAUL H. MAYO

INTRODUCTION

Dr. Daniel Lichtenstein defined the key elements of lung ultrasonography (LUS) with the publication of a series of landmark articles that described the important features and the standard semiology of the field. Based on his original work, there have been numerous subsequent studies from other groups which have served to further validate and define the clinical applications of LUS. LUS is easy to learn, simple to perform, and has strong utility for the critical care that are well supported by the literature, in particular for the evaluation of respiratory failure.
BASIC PRINCIPLES OF LUS

Air-filled lung at the pleural surface prevents visualization of normal lung parenchyma owing to intense reflection of ultrasound that occurs at the interface of the aerated lung and overlying chest wall. The clinical utility of LUS in the critically ill is based on two factors: (1) in cases of respiratory distress or failure, over 90% of attributable lung pathology will contact the pleura at some point in the thorax, revealing identifiable pathologic patterns to the provider at the pleural surface and (2) these patterns can be correlated with discrete causes of respiratory dysfunction \[1,2\].
MACHINE REQUIREMENTS

LUS may be performed with a wide variety of ultrasound machines with two-dimensional (2D) scanning capability. A 3.5 to 5.0 MHz transducer similar to one used for cardiac applications is used for the entire spectrum of applications. Higher frequency (7.5 to 10 MHz) linear probes work well for identification of lung sliding and detailed characterization of pleural morphology.
PERFORMANCE OF LUS

By convention, the transducer is held in a longitudinal scanning plane. The transducer should be held like a pen, perpendicular to the chest wall with the transducer orientation marker pointing cephalad. The screen marker should be set to the left upper side of the screen. This being the case, cephalad structures will be projected to the left on the screen, whereas those that are caudal will be projected to the right on the screen. The scanning axis is perpendicular to the pleural surface. In areas of the thorax where the pleural surface is curvilinear, the probe is adjusted to obtain a perpendicular to the pleural surface, requiring the operator to tilt the transducer to ensure proper orientation of the ultrasonography beam. Proper probe orientation results in a horizontally orientated pleural line on the screen.

Unlike a chest radiograph, where an entire view of both hemithoraces is obtained in one image; thoracic ultrasonography relies on examining the pleural surfaces at multiple sites over each hemithorax, thus creating an image map of the lungs that is the summation of multiple tomographic cuts produced by movement of the ultrasonography scanning plane over the thorax. Many different scanning protocols have been proposed for LUS. Most divide the thorax into the anterior area, bordered by the sternum and the anterior axillary line; the lateral area, bordered by the anterior axillary and posterior axillary lines; and the posterior area, bordered by the posterior axillary line and the spine. Investigators designate specific points within these areas for examination and assign point values to the focal findings at each point. This is useful for research purposes, but impractical for clinical practice. The simplest protocol is that proposed by Lichtenstein that examines three defined points on each hemothorax in the anterior, lateral, and posterolateral area with characterization of LUS findings at each site [2]. An alternative approach is to perform a series of adjacent scan lines over the chest in order to define areas of abnormality that require more focused scanning (Chapter 11 Video 11.1).

The importance of examining the posterolateral chest is emphasized for the critically ill patient, given that the majority of pleural effusions and consolidations are found in the dependent hemithoraces. To adequately image this area, the transducer base is pressed into the mattress with the probe face angled anteriorly. Alternatively, the patient may be rolled to a lateral decubitus position to fully expose the posterior thorax.
IMAGING PATTERNS IN LUS

Pleural line artifacts and associated appearances of lung and pleural pathology described in the following sections are differentially produced according to the ratio of fluid and air produced by the various disease processes. These artifacts and patterns include analysis of the pleural line; the horizontal appearing reverberation artifacts seen in “dry” lung (A lines); the vertical appearing artifacts seen with interstitial fluid (B lines); the airless or fluid-filled lung seen in alveolar consolidation; and the accumulation of fluid seen with pleural effusions.
MAIN LUS PATTERNS

Novice lung ultrasonographers are often challenged by the lack of visually familiar anatomical correlates that are seen when scanning other organs such as the heart or kidney whose boundaries can be well delineated. Many lung images are not intuitively obvious to the novice, given that the condition of the lung is often abstracted from artifactual linear echogenic patterns deep to the pleural line. These patterns are few, discrete, and easy to master. The key findings of LUS for critical care applications are as follows:
NORMAL ANATOMY

On ultrasonography examination, the chest wall consists of skin overlying a layer of soft tissue and muscle covering the rib cage. Below the inner surface of the ribs lies the parietal pleura, against which the outer surface of lung, the visceral pleura, moves in respirophasic and cardiophasic synchrony. The rib edges form a distinctive hyperechoic curvilinear line. The pleural line is the first horizontal hyperechoic line just below the ribs and represents the interface between parietal and visceral pleura (Chapter 11 Video 11.2).

The interface of visceral and parietal pleura is readily visible with ultrasonography. Deep to the visceral pleura are the air-filled alveoli within lobules that are subtended by the interlobular septa. These septa insert into the visceral pleura, but cannot be seen under normal conditions, because their width is below the resolution of standard diagnostic ultrasonography transducers. With normally aerated lung, ultrasonography is intensely reflected from the pleural surface, so that the air-filled lung is not visible as an identifiable structure. It is only when the interlobular septae or the alveolar compartment underlying the visceral pleura are diseased that they become visible to the examiner. These resulting patterns allow ultrasonography to discriminate normal from abnormal lung.
FINDINGS OF LUS

Lung Sliding

With the transducer in a longitudinal orientation, perpendicular to the skin surface, and centered between two adjacent ribs; the pleural line is first located as detailed above, followed by identification of the dynamic movement of the pleural surfaces during the respiratory cycle. This movement, seen as a shimmering mobile pleural line that moves in synchrony with the respiratory cycle, is called lung sliding (Chapter 11 Video 11.3). A related finding is lung pulse, whereby the pleural line moves with cardiophasic movement caused by transmitted cardiac pulsations (Chapter 11 Video 11.4).

The identification of lung sliding or lung pulse excludes the presence of a pneumothorax at the site of transducer application with certainty [3]. Lung sliding and pulse can only be seen when the ultrasound waves propagate to the visceral pleura. When pleural air is interposed between the pleural surfaces, as that occurs with pneumothorax, the air acts as a barrier to ultrasound, so the movement of the underlying visceral pleura cannot be seen. In this case, lung sliding and lung pulse will be absent (Chapter 11 Video 11.5).

As air within the pleural space usually distributes to the anterior thorax in the supine patient, the critically ill patient is ideally positioned to examine for pneumothorax. Multiple rib interspaces sites may be rapidly examined for sliding lung over both hemithoraces, so that the intensivist can promptly and confidently rule out a clinically significant pneumothorax with superior accuracy to chest radiography [3–5].

Although the presence of lung sliding rules out the presence of pneumothorax at the site being examined, the absence of lung sliding is not diagnostic of pneumothorax. Loss of lung sliding may occur in other processes that reduce the movement of the visceral pleura such as pleural symphysis from inflammatory, neoplastic, or therapeutic pleurodesis. Mainstem bronchial intubation or occlusion (e.g., mucus plug, blood clot, foreign body, and tumor) will also ablate lung sliding on the side of the blockage.

In summary, the presence of lung sliding is a very useful sign, because it rules out the possibility of a pneumothorax being present. The absence of lung sliding is less useful, and always requires the clinician to consider whether there might be an alternative explanation for the lack of lung sliding.

Lung Point
When faced with the loss of lung sliding, identifying a lung point can confirm the presence of pneumothorax. The lung point represents the border of the pneumothorax, where the partially collapsed lung interfaces with the air-filled pneumothorax space. Some pneumothoraces are total, but most are partial with some remaining apposition of the visceral and parietal pleura at some point in the thorax, usually lateral or posterior depending on the size of the pneumothorax. A lung point is described as the intermittent respirophasic appearance of lung sliding from the edge of the screen (Chapter 11 Video 11.6). Although 100% specific for pneumothorax, lung point has only a 66% sensitivity for detection of pneumothorax [3].

A Lines

The normally aerated lung yields characteristic air artifacts called “A lines.” An A line is a horizontally orientated line that is deep to the pleural line and separated by the same distance as the probe is to the pleural line (Chapter 11 Video 11.7). The A line is a reverberation of the pleural line, caused by echoes which reflect off of the visceral pleura owing to the inability of ultrasound to penetrate aerated lung tissue. The reflected pulse returns to the probe face and is reflected off of its surface to be in turn reflected back from the pleural line. When this pulse returns to transducer, it is interpreted by the ultrasound machine as arising from an identical, but more distant tissue plane. This is known as a reverberation artifact and occurs when there is an air–tissue interface deep to the probe. A lines can appear singly or multiply and are separated from each other by the same distance. When A lines appear with lung sliding, this represents a normal aeration pattern. When present without sliding lung, A lines represent either air between the visceral and parietal pleura (i.e., a pneumothorax) or aerated lung in association with lack of lung sliding as might occur with pleurodesis from inflammation or intervention.

B Lines

Using standard scanning technique with depth set to examine deeper structures, LUS may yield a characteristic pattern of artifact termed B lines. B lines have several distinct characteristics, as follows (Chapter 11 Video 11.8).

B lines are vertical in orientation and may occur as one or more per field. They originate at the pleural interface. They extend ray-like to the bottom/far periphery of the screen. They move in synchrony with lung sliding (although mobility is not
required, as in the case of B lines in the absence of lung sliding). They are hyperechoic. They efface A lines at their point of intersection.

B lines reflect the presence of a process that infiltrates or widens the interlobular septae of the lung, such as inflammation, neoplasm, or scarring; or that fills the alveolar space [6,7]. The presence of B lines is strongly correlated with alveolar or interstitial pattern abnormalities on computed tomography (CT) scan (ground-glass or reticular pattern abnormality) [8]. Depending on the disease process that is causing the B lines, they may be focal, scattered, or diffuse in distribution. Like any radiographic abnormality on standard chest radiograph or chest CT, clinical correlation is required to determine the cause of the B lines. More than two B lines in a single field are considered significant, with the exception that in normal individuals, several B lines may be present in the basilar-dependent rib interspaces. Pneumonia may manifest with focal B lines detected in the segment or lobe that is involved. Cardiogenic pulmonary edema (CPE) is associated with profuse, bilateral, and often anterior B lines, whereas idiopathic pulmonary fibrosis results in scattered, irregularly appearing B lines in association with pleural line irregularity (Chapter 11 Video 11.9).

The artifacts that are sometimes confused with B-lines include Z lines and E lines. Z-lines are artifacts arising from the pleural line, but attenuate before the periphery and are not as discrete B lines. Z lines have no pathologic significance. E Lines are vertical appearing artifacts that arise proximal to the pleural line from subcutaneous emphysema.

As B lines originate from the visceral pleural surface, their presence indicates that the lung is fully inflated at the site of the transducer application to the chest wall. The presence of B lines therefore rules out a pneumothorax [9]. Loss of lung sliding may occur in ARDS, because the lung is so diseased and the tidal volume so low that it could cause loss of pleural movement. Multiple B lines are characteristic of ARDS, so their presence assures the clinician that no pneumothorax is present, if this is a concern.

**Consolidation**

Consolidated lung yields a characteristic tissue density pattern on ultrasound examination (Chapter 11 Video 11.10) [10]. Consolidated
lung has an echogenicity that is similar to liver (sonographic hepatization of the lung). If the bronchial structures that supply the affected consolidated lung are patent, the consolidated lung may have sonographic air bronchograms within it, appearing as small hyperechoic foci within the parenchyma. These represent small amounts of air in the bronchi. They may be mobile, reflecting movement of air within the bronchus owing to respiratory activity (Chapter 11 Video 11.11). Dynamic air bronchograms are highly suggestive of pneumonia as the cause of the consolidation [11]. The examiner may localize consolidation to a specific lobe or segment of the lung. The finding of consolidation with LUS is strongly correlated with results of chest CT [8]. The finding of consolidation on LUS is purely descriptive, and similar to the finding of consolidation on chest radiography or chest CT. Any process that renders the alveolar compartment airless will demonstrate consolidation on LUS or with other radiographic techniques. All causes of airless lung, such as atelectasis (compressive, resorptive, or cicatricial), infiltrative processes (tumor, purulent material as in pneumonia), or severe pulmonary edema with complete filling of the alveolar compartment will yield the ultrasonographic finding of lung consolidation. LUS identifies the consolidation; the clinician determines its cause.
Differentiating Causes of Acute Respiratory Failure and Dyspnea

Knowledge of LUS patterns allows the intensivist to improve the accuracy of diagnosis of acute respiratory failure when compared to use of standard clinical testing and assessment [12,13]. Given the utility of LUS to identify the cause of respiratory failure, the thoracic ultrasound examination may replace standard chest radiography as a more effective and efficient imaging modality [14–16]. When evaluating the patient with dyspnea and/or respiratory failure, the critical care clinician associates various profiles described below with the corresponding cause of respiratory failure compromise. This allows for early categorization of the disease process.

Generalized A Lines with Lung Sliding

This normal aeration pattern is seen among healthy patients; but when it is associated with dyspnea, the diagnostic possibilities include (1) the airway compartment (Chronic Obstructive Pulmonary Disease [COPD] or asthma), (2) the vascular compartment (pulmonary embolism), or (3) non-pulmonary causes such as neurologic, neuromuscular, metabolic, and toxic. This pattern rules out diseases that compromise the alveolar and/or interstitial compartment (pulmonary edema, pneumonia, fibrosis, etc.) or the pleural compartment. Identification of a normal aeration pattern of the dyspneic patient where pulmonary embolism is a concern requires the intensivist to perform a study for venous thromboembolism (see Chapter 92 on Venous Thromboembolism).

A Lines, Absence of Lung Sliding, Presence of Lung Point

When lung sliding is absent with A lines, pneumothorax is a possibility. For this situation, identification of a lung point confirms that there is a pneumothorax. If no lung point is identified, other methods are required to confirm if there is a pneumothorax, given the low sensitivity of lung point. The presence of lung pulse, B lines, or consolidation also rules out pneumothorax at the interspace being examined. Multiple interspaces are examined in a short period of time.
**Alveolar/Interstitial Disease: B Line Patterns**

Detection of profuse B lines at multiple symmetric points over the anterior chest indicates a high probability of an alveolar and/or interstitial process. CPE with profuse B line pattern is associated with a smooth pleural line morphology. This requires examination of the pleural line with the high frequency linear vascular probe. A rare cause of unilateral profuse B line pattern with smooth pleural morphology is unilateral CPE related to asymmetric mitral valve regurgitation.

Detection of multiple focal B lines with asymmetric distribution suggests primary lung injury pattern such as pneumonia, acute respiratory distress syndrome (ARDS), or other alveolar/interstitial process. For instance, when B lines are detected from subsegmental, segmental, lobar, or unilateral distribution, or involving one hemithorax with A line pattern for the rest of the lung, pneumonia is a prime consideration. Primary lung injury results in irregular pleural morphology. This requires examination of the pleural line with the high-frequency linear vascular probe. Thus, depending on the pattern of B profiles over the hemithorax (unilateral vs bilateral; irregular pleural line; sliding or non-sliding lung; sparing or uniform areas), the provider can differentiate CPE versus primary lung injury as the cause of respiratory failure.

**Alveolar Consolidation Pattern**

Alveolar consolidation is readily identified with LUS. It may appear as small multifocal areas of consolidation immediately below the pleural interface or in subsegmental, segmental, lobar, whole lung pattern with unifocal or multifocal distribution. As with chest radiography and chest CT, the finding of alveolar consolidation pattern with LUS is descriptive and not diagnostic, given that there are many causes for alveolar consolidation.

For pneumonia, the consolidation appears as tissue density without volume loss (Chapter 11 Video 11.10). The interface between the pleural surface and the consolidation is linear, whereas the interface between the consolidation and the adjacent aerated lung is irregular and often is associated with comet tail artifacts. This irregular interface is called the “shred sign” (Chapter 11 Video Clip 11.12). Pneumonias often contain dynamic air bronchograms, which appear as mobile, branching, and hyperechoic within the parenchyma (Chapter 11 Video 11.11). Although suggestive of pneumonia, mobile air bronchograms may be found in association with non-pneumonia consolidation; a hypoechoic area with well-defined borders within an area of alveolar consolidation is consistent with necrosis or abscess (Chapter 11 Video 11.13).
Atelectasis of lung results in an alveolar consolidation pattern that can be readily identified with LUS. The mechanism of the atelectasis may differ (compressive, resorptive, or cicatricial), but there is a characteristic loss of lung volume in association with the alveolar consolidation. Mobile air bronchograms are uncommon, although static air bronchograms are often present, unless the cause for the atelectasis is complete endobronchial occlusion [11].

A common cause of alveolar consolidation is that which occurs with pleural effusion. Compressive atelectasis from a pleural effusion causes the atelectatic lung to float within the effusion often in association with respirophasic or cardiophasic movement of the lung (Chapter 11 Video 11.14). Areas of posterior basilar alveolar consolidation commonly occur in patients on ventilatory support. The dual mechanism of compressive and resorptive atelectasis results in the airless lung that reinflates when the patient is successfully extubated. Differentiation from pneumonia may be challenging and requires clinical correlation. Endobronchial occlusion by mucus; tumor; foreign body aspiration; or block of the left mainstem bronchus with the endotracheal tube balloon (because of unintentional right mainstem bronchial intubation) results in resorptive atelectasis that is detected as alveolar consolidation with LUS. Bronchial occlusion results in absence of mobile air bronchograms. If the blockage is at the mainstem bronchial level, the affected lung undergoes major volume loss with associated marked ipsilateral shift of mediastinal and cardiac structures. This can occur rapidly if the patient is on a high FiO₂ as is the case immediately following endotracheal intubation.
CLINICAL APPLICATIONS OF LUS

Clarification of the Ambiguous Chest Radiograph

The technique of the intensive care unit (ICU) chest radiograph is often suboptimal. The anteroposterior projection combines with rotation, penetration, and density summation artifact to make interpretation difficult. Chest radiography results in a 2D representation of a complex structure, whereas thoracic ultrasonography yields a three-dimensional representation of the thoracic compartment by virtue of the multiple tomographic planes used in the examination. LUS may replace chest radiography for evaluation of the dyspneic patient; for identification of consolidation related to pneumonia; and for the evaluation of pleuritic chest pain [14–16]. The routine use of LUS was associated with reduced use of chest radiography and chest CT in a medical ICU [17]. An ambiguous chest radiograph requires clarification with LUS.

As performance of LUS is superior to the standard ICU chest radiograph for detection of normal aeration pattern, alveolar/interstitial pattern, consolidation, pneumothorax, and pleural effusion [8]; the argument may be made that LUS could largely replace chest radiography in the ICU [18]. Although chest radiography does remain useful for determining the location of a variety of intrathoracic devices (see Chapter 179 Chest Radiographic Examination), the location of central venous catheters may, in many cases, be determined with ultrasonography (See Chapter 6 Central Venous Catheters).

Differentiation of ARDS from Cardiogenic Pulmonary Edema

Copetti et al. demonstrated the ability of LUS to discriminate between acute respiratory distress syndrome (ARDS) and CPE [19]. The most specific sign for ARDS was the finding of both an area of normal aeration within a single interspace co-existing with a focus on B lines/interstitial syndrome. Such a pattern was found in 100% of ARDS patients and 0% of CPE patients. Pleural line abnormalities such as thickening >2 mm, coarse irregular appearance, or subpleural consolidations were found in 100% of ARDS patients and 25% of CPE patients. Profuse B line pattern with a smooth pleural surface was highly suggestive of CPE. The finding of new onset B lines bilaterally during cardiac stress testing is indicative of inducible cardiac ischemia with increase in left-sided filling pressures [20]. An increase in extravascular lung water—as assessed independently by chest CT, chest X-ray, and thermodilution techniques—is associated
with B lines [21].

**Prediction of Extubation Failure**

The amount of extravascular lung water and non-aerated lung can be accurately estimated using the LUS scoring system proposed by Rouby et al. [22]. In their scoring system, a value of 0 is assigned to any interspace examined which revealed A lines with sliding lung, a value of 1 to interspaces with regularly spaced B lines consistent with interlobular septal thickening, a value of 2 to interspaces with confluent B lines filling the visualized interspace, and a value of 3 was assigned to interspaces with consolidation. Assigning a score to 6 interspaces over each hemithorax led to a maximum LUS score of 36. When performing LUS scores before and after a 30-minute spontaneous breathing trial (SBT), an increase in the LUS score of more than 4 points predicted extubation failure. Additionally, any end-SBT LUS score >17 strongly predicted extubation failure.

**Measurement of Lung Recruitment with PEEP**

The above LUS score can also be used to predict the effects of positive end-expiratory pressure (PEEP) in ARDS patients [23]. When varying PEEP levels from 0 to 15, a decrease of 8 points in the LUS score described above using the higher PEEP, resulted in an average increase of lung volume >600 mL. If the LUS score increased by 4 or less, the volume increased by an average of 75 to 450 mL. The authors of this report caution that they could not distinguish whether the augmentation of lung volume resulted from lung recruitment or from overdistention of lung.

**Diagnosis of Pneumonia**

LUS is useful in establishing the diagnosis of pneumonia and following its evolution [24,25]. Of interest to the intensivist, the resolution of ventilator associated pneumonia (VAP) with antibiotic therapy can tracked with LUS [26], and the combination of LUS with sputum analysis is useful for the diagnosis of VAP [27].

**Algorithmic Diagnosis of Respiratory Failure**

Dr. Lichtenstein has developed a useful algorithm for the use of LUS in determining the cause of respiratory failure (the bedside lung ultrasound in emergency [BLUE] protocol) [2]. Using a simple three-point examination technique and simple LUS signs, the algorithm identified the etiology of respiratory failure in a high proportion of cases.
Estimates of Left Atrial Pressure

Patients with symptomatic CPE have a bilateral B line pattern. Conversely, if the patient has A line pattern with lung sliding, there is a high probability that the pulmonary occlusion pressure is below 18 mm Hg and probably less that 12 mm Hg [28]. Beyond its clinical utility in diagnosis of respiratory failure, this information has application during cardiac stress testing. EKG monitoring and serial segmental wall analysis with echocardiography are standard means of detecting ischemia during the stress test. The sudden appearance of B lines coincident with the onset of dyspnea while under exercise load is consistent with elevation of left atrial pressures with resultant CPE precipitated by cardiac ischemia [20].

Combination of LUS with Echocardiography

In evaluating patients with acute respiratory failure, Bataille et al. reported that the addition of echocardiography to LUS was superior to performing LUS alone [29]. Sekiguchi et al. confirmed that LUS is productively combined with echocardiography for the evaluation of respiratory failure [30].

Diagnosis of Pulmonary Embolism

Koenig et al. and Nazerian et al. both found that LUS combined with echocardiography and DVT study is a means of reducing unnecessary chest CT angiograms when pulmonary embolism is a diagnostic consideration. A definite alternative diagnosis of pulmonary embolism using ultrasonography excluded pulmonary embolism with a high level of certainty [31,32]. Mathis et al. reported that pulmonary emboli commonly result in small areas of consolidation immediately deep to the pleural interface with preferential distribution to the lower lobes of the lung [33]. This is a difficult area to image in the critically ill patient who is generally in supine position, so their results have uncertain application for the intensivist.

Timing of Chest Tube Removal

Maury et al. used LUS to document lung expansion following chest tube insertion for pneumothorax [34]. Once the lung is fully inflated by LUS criteria, the chest tube is clamped and LUS performed to observe for
recurrence of the PTX. If there is no recurrence by LUS, the chest tube may be safely removed. The investigators found that this method was superior to standard chest radiography. From a practical point of view, this method offers a convenient, efficient, and cost-effective means of timing the removal of chest tube.

**LUS for Guidance of Procedures**

LUS may be used to guide transthoracic needles to biopsy peripheral lung lesions that abut the chest wall and thus are visible, given that no aerated lung is interposed [35]. Similarly, intraparenchymal lung abscess can be drained if clinically indicated [36].

**Utility of LUS for Thoracic Trauma**

The utility of LUS for thoracic trauma is reviewed in Chapter 43 on Thoracic and Cardiac Trauma.

**Utility of LUS for Airway Management**

The utility of LUS for airway management is reviewed in Chapter 8 on Airway Management.
REFERENCES

Thoracentesis is an invasive procedure that involves the introduction of a needle, cannula, or trocar into the pleural space to remove accumulated fluid or air. Although a few studies have critically evaluated the clinical value and complications associated with it [1–6], most studies concerning thoracentesis have dealt with the interpretation of the pleural fluid analyses [7–11].

**INDICATIONS**

Although history (cough, dyspnea, or pleuritic chest pain) and physical findings (dullness to percussion, decreased breath sounds, and decreased vocal fremitus) suggest that an effusion is present, chest radiography or ultrasonic examination is essential to confirm the clinical suspicion. Thoracentesis can be performed for diagnostic or therapeutic reasons. When done for diagnostic reasons, the procedure should be performed whenever possible before any treatment has been given to avoid confusion in interpretation. Analysis of pleural fluid has been shown to yield clinically useful information in more than 90% of cases. The four most common diagnoses for symptomatic and asymptomatic pleural effusions are malignancy, congestive heart failure (CHF), parapneumonia, and postoperative sympathetic effusions. A diagnostic algorithm for evaluation of a pleural effusion of unknown etiology is presented in Figure 12.1. In patients whose exudative pleural effusion remains undiagnosed after thoracentesis, closed pleural biopsy or thoracoscopy should be considered. Thoracoscopy provides for visualization of the pleura and directed biopsy, and yields a diagnosis in more than 80% of patients with recurrent pleural effusions that are not diagnosed by repeated thoracentesis, closed pleural biopsy, or bronchoscopy.
Therapeutic thoracentesis is indicated to remove fluid or air that is causing cardiopulmonary embarrassment, or for relief of severe symptoms. Definitive drainage of the pleural space with a thoracostomy tube must be done for a tension pneumothorax (PTX) and should be considered for: a PTX that is slowly enlarging; any size PTX in the mechanically ventilated patient; hemothorax; or the instillation of a
sclerosing agent after drainage of a recurrent malignant pleural effusion.
CONTRAINDICATIONS

Absolute contraindications to performing a thoracentesis are an uncooperative patient; a lack of expertise in performing the procedure; and the presence of a coagulation abnormality that cannot be corrected. Relative contraindications to a thoracentesis include entry into an area where known bullous lung disease exists; a patient on positive end-expiratory pressure (PEEP); and a patient who has only one “functioning” lung (the other having been surgically removed or that has severe disease limiting its gas exchange function).
A number of prospective studies have documented that complications associated with the procedure are not infrequent [1–6,12]. The overall complication rate has been reported to be as high as 50% to 78% and can be further categorized as major (15% to 19%) or minor (31% to 63%) [12]. Complication rates appear to be inversely related to experience level of the operator; the more experienced the operator, the fewer the complications. Although death due to the procedure is infrequently reported, complications may be life threatening.

Major complications include PTX; bleeding (e.g., hemopneumothorax, hemoperitoneum, and hematoma); hypotension; soft tissue infection; empyema; spleen or liver puncture; and reexpansion pulmonary edema. The reported incidence of PTX is up to 30% (with most studies reporting rates of nearly 12%) and up to one-third to one-half of those with demonstrated PTX requiring subsequent intervention [2,12]. Tube thoracostomy should be considered for any PTX that is large or progressive and in any patient that is mechanically ventilated or symptomatic after the procedure. Several nonrandomized studies involving spontaneously breathing patients undergoing ultrasound-guided thoracentesis (USGT) performed by trained operators have demonstrated a reduction in the rate of PTX to less than 2% [5,6,13]. The risk of PTX for patients receiving positive-pressure mechanical ventilation is approximately 1% to 7% with the use of USGT [1,3]. The use of PEEP does not appear to increase the risk of PTX for USGT [11].

Various investigators have reported associations (“risk factors”) between PTX and underlying lung disease (chronic obstructive pulmonary disease, prior thoracic radiation, prior thoracic surgery, and lung cancer); needle size and technique; number of passes required to obtain a sample; aspiration of air during the procedure; operator experience; use of a vacuum bottle; smaller size of the effusion; and mechanical ventilation versus spontaneously breathing patients [2,12]. Small sample sizes and observational study design limit the generalization of reported findings to allow for the delineation of a clear risk profile for the development of a PTX due to thoracentesis. The presence of baseline lung disease; low level of operator experience with the procedure; lack of use of ultrasound guidance; and the use of positive-pressure mechanical ventilation appear for now to be the best-established risk factors in the literature. Recognition and optimization of modifiable risk factors has been shown to improve the safety of thoracentesis [5,6,13]. Given the evidence of the value of ultrasound guidance in the performance of thoracentesis [1,3,5,6,13–16], the Accreditation Council
for Graduate Medical Education (ACGME) has stated that effective July 2012 pulmonary/critical care fellows “must demonstrate competence in procedural and technical skills, including: use of ultrasound techniques to perform thoracentesis and place intravascular and intracavitary tubes and catheters.” Thoracic ultrasound techniques for the sampling/removal of pleural fluid are described in more detail below.

Although PTX is most commonly caused by laceration of lung parenchyma, room air may enter the pleural space around or through a thoracentesis needle or catheter that is open to room air when a spontaneously breathing patient takes a deep breath (intrapleural pressure is subatmospheric). The PTX may be small and asymptomatic, resolving spontaneously, or large and associated with respiratory compromise, requiring chest tube drainage. Hemorrhage can occur from laceration of an intercostal artery or unintentional puncture of the liver or spleen, even if coagulation studies are normal. The risk of intercostal artery laceration is greatest in the elderly because of increased tortuosity of their vessels. This last complication is potentially lethal, and risk is minimized at sites 9 to 10 cm lateral to the spine (essentially the posterior axillary line, and this is the preferred puncture site, assuming accessibility of the fluid collection) [17,18].

Hypotension may occur during the procedure (as part of a vasovagal reaction or tension PTX) or hours after the procedure (uncommon, but most likely because of reaccumulation of fluid into the pleural space or the pulmonary parenchyma from the intravascular space). Hypotension in the latter settings responds to volume expansion; it can usually be prevented by limiting pleural fluid drainage to 1.5 L or less or alternatively by using serial measurements of pleural pressure (manometry) during large volume thoracentesis to determine a “safe” volume of fluid to be removed (described elsewhere) [19]. Other major complications are rare and may include implantation of tumor along the needle tract of a previously performed thoracentesis; venous and cerebral air embolism (the so-called pleural shock); and accidental shearing of the catheter in the pleural space [12].

Minor complications include dry tap or insufficient fluid; pain; subcutaneous hematoma or seroma; anxiety; dyspnea; and cough. Reported rates for these minor complications range from 16% to 63%
Dry tap and insufficient fluid are technical problems and expose the patient to increased risk of morbidity because of the need to perform multiple needle passes or repeated thoracentesis attempts at an alternate site. Pain may originate from parietal pleural nerve endings from inadequate local anesthesia; unintentional scraping of rib periosteum; or piercing an intercostal nerve during a misdirected needle thrust.
PROCEDURES

General Considerations

The most common techniques for performing thoracentesis are catheter-over-needle; needle only; and needle under direct sonographic guidance (multiple commercially available kits available). The catheter-through-needle technique has been used much less frequently over the past few decades. Performing thoracentesis without ultrasound guidance (using auscultation and percussion exam techniques to establish a fluid level) is suggested only in the presence of a large, free-flowing effusion and limited availability of ultrasound. Otherwise, USGT is the method of choice.

Technique for Diagnostic Sampling of a Large, Freely Flowing Pleural Effusion (Clinical Exam Guided)

1. Obtain a lateral decubitus chest radiograph to confirm a large, free-flowing pleural effusion. This is only required if ultrasonography is not available.

2. Describe the procedure to the patient and obtain written informed consent. Operators should be thoroughly familiar with the procedure that they will perform, and should receive appropriate supervision from an experienced operator before performing thoracentesis on their own.

3. With the patient sitting, arms at sides, mark the inferior tip of the scapula on the side to be tapped. This approximates the eighth intercostal space and should be the lowest interspace punctured, unless it has been previously determined by sonography that a lower interspace can be safely entered, or chest radiographs and sonography show the diaphragm to be higher than the eighth intercostal space.

4. Position the patient sitting at the edge of the bed, comfortably leaning forward over a pillow-draped, height-adjusted, bedside table (Fig. 12.2). The patient’s arms should be crossed in front to elevate and spread the scapulae. An assistant should stand in front of the patient to prevent any unexpected movements.

5. Percuss the patient’s posterior chest to determine the highest point of the effusion. The interspace below this point should be entered in the posterior axillary line, unless it is below the eighth intercostal space.
Gently mark the superior aspect of the rib in the chosen interspace with your fingernail (The inferior portion of each rib contains an intercostal artery and should be avoided.).

5. Cleanse a wide area with 0.05% chlorhexidine or 10% povidone–iodine solution and allow it to dry. Using sterile technique, drape the area surrounding the puncture site.

7. Perform a time out and anesthetize the superficial skin with 2% lidocaine using a 25-gauge needle. Change to an 18- to 22-gauge needle, 2 inches long, and generously anesthetize the deeper soft tissues, aiming for the top of the rib. Always aspirate through the syringe as the needle is advanced and before instilling lidocaine to ensure that the needle is not in a vessel or the pleural space. Carefully aspirate through the syringe as the pleura is approached (the rib is 1 to 2 cm thick). Pleural fluid enters the syringe on reaching the pleural space. The patient may experience discomfort as the needle penetrates the well-innervated parietal pleura. Be careful not to instill anesthetic into the pleural space; it is bactericidal for most organisms, including *Mycobacterium tuberculosis*. Place a gloved finger at the point on the needle where it exits the skin (to estimate the required depth of insertion) and remove the needle.

8. Attach a three-way stopcock to a 20-gauge, 1.5-inch needle and to a 50-mL syringe. The valve on the stopcock should be open to the needle to allow aspiration of pleural fluid during needle insertion.

9. Insert the 20-gauge needle (or the catheter-over-needle apparatus) into the anesthetized tract with the bevel of the needle down and always aspirate through the syringe as the needle/catheter-over-needle is slowly advanced. When pleural fluid is obtained using the needle-only technique, stabilize the needle by attaching a clamp to the needle where it exits the skin to prevent further advancement of the needle into the pleural space. Once pleural fluid is obtained with the catheter-over-needle technique, direct the needle-catheter apparatus downward to ensure that the catheter descends to the most dependent area of the pleural space. Advance the catheter forward in a single smooth motion as the inner needle is simultaneously pulled back out of the chest.

10. Once you have reached a point when pleural fluid can easily be obtained, fill a heparinized blood gas syringe from the side port of the three-way stopcock for measurement of fluid pH. Express all air bubbles from the sample, cap it, and place it in a bag containing iced slush for immediate transport to the laboratory.

11. Fill the 50-mL syringe and transfer its contents into the appropriate collection tubes and containers. Always maintain a closed system
during the procedure to prevent room air from entering the pleural space. For most diagnostic studies, 50 to 100 mL should be an ample volume [20,21]. Always ensure that the three-way stopcock has the valve closed toward the patient when changing syringes.

2. When the thoracentesis is completed, remove the needle (or catheter) from the patient’s chest as they hum or perform a Valsalva maneuver. Apply pressure to the wound for several minutes, and then apply a sterile bandage.

3. A routine chest radiograph after thoracentesis is not generally indicated for most asymptomatic, nonventilated patients. Obtain a post-procedure upright end-expiratory chest radiograph if air was aspirated during the procedure; if PTX is suspected by developing signs or symptoms; or if multiple needle passes were required [1,12,22]. Whether a post-thoracentesis chest radiograph is necessary for patients who are mechanically ventilated is controversial [3,22]; however, it should be remembered that any PTX in a ventilated patient creates the risk that a tension PTX may occur rapidly.

**FIGURE 12.2** Catheter-over-needle technique for thoracentesis of freely flowing pleural field. A: The patient is comfortably positioned, sitting up and leaning forward over a pillow-draped, height-adjusted,
bedside table. The arms are crossed in front of the patient to elevate and spread the scapulae. The preferred entry site is along the posterior axillary line. B: The catheter apparatus is gently advanced through the skin and across the upper surface of the rib. The needle is advanced several millimeters at a time while continuously aspirating through the syringe. C: As soon as the parietal pleura has been punctured, pleural fluid will appear in the syringe. D: Before the catheter is advanced any farther, the apparatus is directed downward. E,F: In rapid sequence, the catheter is advanced fully to the chest wall and the needle withdrawn from the apparatus. The one-way valve in the apparatus maintains a closed system until the operator manually changes the position of the stopcock to allow drainage of the pleural fluid.

Technique for Therapeutic Removal of Freely Flowing Fluid

To perform the technique for therapeutic removal of freely flowing fluid, steps 1 to 7 should be followed as described previously. Removal of more than 100 mL pleural fluid generally involves placement of a catheter into the pleural space to minimize the risk of PTX from a needle during this longer procedure. Commercially available kits generally use a catheter-over-needle system, although catheter-through-needle systems are still available in some locations. Each kit should have a specific set of instructions for performing this procedure, and all will generally mirror the procedure described above. Operators should be thoroughly familiar with the recommended procedure for the catheter system that they will use and should receive appropriate supervision from an experienced operator before performing thoracentesis on their own.

Technique for Removal of Freely Moving Pneumothorax

The technique for removal of freely moving PTX is as follows:

1. Follow the same catheter-over-needle protocol described for removing freely moving fluid, but position the patient supine with the head of the bed elevated 30 to 45 degrees.

2. Prepare the second or third intercostal space in the anterior midclavicular line (this avoids hitting the more medial internal mammary artery) for the needle and catheter insertion.
Have the bevel of the needle facing up, and direct the needle upward so that the catheter can be guided toward the superior aspect of the hemithorax.

Air can be actively withdrawn by syringe or pushed out when intrapleural pressure is supraatmospheric (e.g., during a cough) as long as the catheter is intermittently open to the atmosphere. In the latter setting, air can leave but not reenter if the catheter is attached to a one-way check-valve apparatus (Heimlich valve) or if it is put to underwater seal.

When local anesthesia and skin cleansing are not possible because a tension PTX is life threatening, perform the procedure without them. If a tension PTX is known or suspected to be present and a chest tube is not readily available, quickly insert a 14-gauge needle and 16-gauge catheter according to the above technique to avoid puncturing the lung. If a tension PTX is present, air escapes under pressure. When the situation has stabilized and the tension PTX has been diagnosed, leave the catheter in place until a sterile chest tube can be inserted.

Utility of Ultrasonography for Guidance of Thoracentesis

Whether to guide simple needle insertion for diagnostic thoracentesis or to perform more complex pleural procedures, the use of ultrasonography should be considered as a key feature of any pleural intervention. Ultrasonography guidance of thoracentesis reduces the rate of PTX [2,23]; facilitates the identification and targeting of the pleural effusion; and is more accurate in determining a safe site for needle insertion than physical examination [24]. It allows for performance of thoracentesis on patients who are on mechanical ventilator support [14] and for targeted insertion of drainage catheters into loculated pleural effusion.

Although this information may provide details regarding the etiology of the effusion, sampling the fluid is often an important part of management, as is the need for pleural interventions that require catheter insertion. There are several considerations when using ultrasonography to guide thoracentesis.

**Equipment**

The ultrasonography examination is performed using a phased-array cardiac probe (3.5 to 5.0 MHz) whose small footprint allows for examination between rib interspaces. A curvilinear abdominal probe may also be used. The linear high frequency probe lacks sufficient penetration to visualize deeper thoracic structures such as atelectatic lung underlying the pleural effusion.

**Scanning Technique**

A series of scan lines are performed over the chest in order to identify and characterize the pleural effusion, and to establish a safe site for needle insertion that avoids injury to adjacent organs.

**Patient Position**

The critically ill patient is generally in the supine position, which makes it difficult to identify a safe site for needle insertion unless the pleural effusion is large, because pleural fluid, unless loculated, assumes a dependent position in the thorax. In the case of a smaller effusion in a supine patient, the effusion will be posterior in location and readily identified by pressing the probe into the mattress with anterior angulation. However, this probe position cannot be duplicated by the needle–syringe assembly, which is a key requirement for safe needle insertion trajectory. In the case of a large effusion, the effusion will be visible with ultrasonography in a more anterior position, with a probe angulation that may be duplicated with the needle–syringe assembly. In the case of a small effusion, if no safe site can be identified with the patient in supine position, the head of the bed may be raised to semirecumbent position and the ipsilateral arm adducted in order to expose the posterolateral chest. The probe is used to scan the lower posterolateral chest to establish a safe site for needle insertion. The limitation of this method is that a team member must hold the patient in position for the entire duration of the procedure. An alternative is to place the patient in a lateral decubitus position with the hemithorax contralateral to the effusion in the dependent position. The pleural effusion is identified by scanning over the posterior
Identification of Fluid

The examiner seeks three characteristic findings that are typical for a pleural effusion.

- An anechoic or relatively hypoechoic space that is surrounded by typical anatomic boundaries. This space represents the pleural effusion.

- Typical anatomic boundaries: This requires unequivocal identification of the chest wall, the surface of the lung, and the diaphragm. The heart may form an anatomic boundary on the left side. Identification of the diaphragm is a critical element of safe site selection as subdiaphragmatic device insertion may result in splenic or hepatic injury. Identification of the diaphragm requires definitive identification of the subdiaphragmatic organs (spleen or liver; and kidneys). The inexperienced scanner may misidentify the hepatorenal or splenorenal space as the diaphragm and consider the overlying liver or spleen to be an echo-dense effusion, because the spaces may appear as a curvilinear structure that may be mistaken for the diaphragm. This dangerous error is avoided by emphasizing the identification of the kidney as a discrete structure that is well below the diaphragm.

- Dynamic changes: This requires identification of dynamic changes that are typical of a pleural effusion such as diaphragmatic movement; lung movement; and movement of internal echogenic elements within the pleural effusion.

Site Selection

Once the pleural effusion is identified, the transducer is moved over the target area in order to identify a safe site for needle insertion that maximizes the distance between the chest wall and the underlying lung while avoiding adjacent anatomic structures such as the diaphragm or heart (on the left side). As much as possible, the examiner holds the probe perpendicular to the chest wall, because this angle is easiest to duplicate with the needle–syringe assembly. Once a suitable site is
identified, it is marked; the depth of needle penetration to access the fluid is measured; and the angle of the probe is determined. This angle will be duplicated by the operator during needle insertion.

A rare complication of thoracentesis is laceration of an intercostal wall vessel with subsequent hemothorax. This risk may be reduced by using the high-frequency vascular probe to scan the proposed needle trajectory. Using color Doppler, identification of a vessel may allow the operator to select an alternative site [25].

**Performance of Needle Insertion**

Once the site is selected, there can be no further patient movement, because this may shift the position of the pleural effusion within the chest cavity relative to the insertion site. The time between the ultrasonography examination and needle insertion is minimized. Immediately before the sterile preparation, the operator rechecks the site, angle, and depth for needle insertion. The thoracentesis is performed with free hand technique by inserting the needle–syringe assembly at the site mark, duplicating the angle at which the probe was held to determine a safe trajectory. Real-time guidance of needle insertion is not required for safe thoracentesis. If a wire is inserted through the needle for Seldinger technique device insertion, some operators identify the wire position before using the dilator. Likewise, final device position may be determined with ultrasonography.

As a routine, the patient should be checked for PTX before the procedure by examining for lung sliding, lung pulse, and/or B lines. Their presence reliably rules out PTX (see Chapter 11 on Lung Ultrasonography). Following the procedure, the examination is repeated. The continued presence of these three signs rules out PTX so reliably that chest radiography is not necessary, and may be misleading [26]. Their absence is strong evidence of a procedure-related PTX.

**Pitfalls of Imaging**

- Skin compression: In the edematous or obese patient, skin compression artifact may cause an underestimation of the depth for successful needle insertion. In this case, the operator pushes the probe into the skin surface in order to improve image quality. This causes indentation of the skin surface at the target site that rebounds when the probe is
removed. This is problematic at the time of needle insertion, because the operator must insert the needle to a depth greater than that measured with indentation of the skin.

- Site mark movement: If lateral force is applied to the skin at the time of marking the insertion site, the skin mark may be moved to a substantial extent. This is of particular concern when accessing a smaller effusion. At the time of needle insertion, the operator takes care to not move the mark site when applying pressure to the skin surface.

- Difficult scanning conditions: It may be difficult to achieve adequate image quality in the massively obese or edematous patient. The pleural effusion may be so echogenic that it could cause uncertainty as to its size or location.
INTERPRETATION OF PLEURAL FLUID ANALYSIS

To determine the etiology of a pleural effusion, a number of tests on pleural fluid are helpful. The initial determination should be to classify the effusion as a transudate or an exudate using the criteria discussed below. Additional studies can then be ordered to help establish a final diagnosis for the etiology of the pleural effusion, especially in the setting of an exudate.

Transudates Versus Exudates

A transudate is biochemically defined by meeting all of the following classic (Light’s) criteria [7]: pleural fluid–serum total protein ratio of less than 0.5; pleural fluid–serum lactate dehydrogenase (LDH) ratio of less than 0.6; and pleural fluid LDH of less than two-thirds the normal serum level. Transudates are generally caused by hydrostatic or oncotic pressure imbalances, or from the migration of pleural fluid from peritoneal or retroperitoneal spaces to the pleural space. An exudate is present when any of the foregoing criteria for transudates are not met. Exudates arise through a variety of mechanisms that result primarily from inflammation of the lung or pleura, impaired lymphatic drainage, or migration of fluid from the peritoneal space.

A wide variety of alternative diagnostic criteria have been studied since Light’s original work was published. Abbreviated criteria with similar diagnostic accuracy, but without the need for concurrent serum measurements, have been proposed [8–10]. A meta-analysis of 8 studies (1,448 patients) indicates that a classic transudate can be identified with equal accuracy by the combination of both pleural fluid cholesterol of less than 45 mg per dL and a pleural fluid LDH less than 0.45 times the upper limit of normal for serum LDH [8]. Clinical judgment will be required when analyzing any borderline test results.

If a transudate is present, generally no further tests on pleural fluid are indicated (Table 12.1). If an exudate is identified, further laboratory evaluation is generally warranted (Fig. 12.1). If subsequent testing does not narrow the differential diagnosis and tuberculous pleuritis is a diagnostic consideration, a percutaneous pleural biopsy should be considered given the improved sensitivity over thoracentesis alone. If mesothelioma is considered a distinct possibility, consideration should be given to proceeding directly to thoracoscopic or open pleural biopsy to provide a large enough tissue sample to optimize diagnostic success.
Thoracoscopy-guided pleural biopsy should be considered in patients with pleural effusion of unknown etiology while following the above-listed evaluation.

**Selected Tests that are Potentially Helpful to Establish Etiology for a Pleural Effusion**

**pH**

Pleural fluid pH determinations may have diagnostic and therapeutic implications [12]. For instance, the differential diagnosis associated with a pleural fluid pH of less than 7.2 is consistent with systemic acidemia; bacterially infected effusion (empyema); malignant effusion; rheumatoid pleuritis; tuberculous effusion; ruptured esophagus, noninfected parapneumonic effusion that needs drainage; paragonimiasis; and urinothorax. Pleural effusions with a pH of less than 7.2 are potentially sclerosis provoking and require consideration for chest tube drainage to aid resolution [12].

**Glucose**

All transudates and most exudates will have pleural glucose levels similar to blood glucose concentrations. Some exudates will have low pleural fluid glucose values (defined as less than 60 mg per dL) and in this situation, the differential diagnosis overlaps with those causes listed above for low pH effusions. Potentially important to note is that whereas pleural glucose levels are not significantly impacted by the duration of time the sample awaits analysis or the presence of air or lidocaine in the same sampling syringe, there can be clinically significant increases (time delay, air) or decreases (lidocaine) noted in the pleural fluid pH by these factors [27]. Therefore, glucose levels may serve as a surrogate for pleural fluid pH if there is any concern that the measured pH may be inaccurate.
Protein, LDH, and Protein Gradient

The main purpose for measuring pleural fluid protein and LDH levels is the separation of transudative from exudative effusions. An additional key point is that the pleural fluid LDH can serve as an indirect reflection of the degree of pleural inflammation, and any effusion classified as an exudate based on LDH criterion alone (and not by protein level as well) suggests the presence of pleural space infection or a malignant effusion. Also, importantly, the serum protein minus pleural fluid protein gradient may be of value in distinguishing a truly transudative effusion due to CHF in a patient who has undergone diuresis, from a truly exudative effusion. If in the setting of a patient who has undergone diuresis for CHF, the protein gradient is greater than 3.1 g per dL (or if greater than 1.2 g per dL when an albumin gradient is measured instead), that effusion is most likely transudative in nature and caused by CHF.

Amylase

A pleural fluid amylase level that is greater than the normal serum level may be seen in patients with acute and chronic pancreatitis; pancreatic pseudocyst that has dissected or ruptured into the pleural space; malignancy; and esophageal rupture. Salivary isoenzymes predominate with malignancy and esophageal rupture, whereas intrinsic pancreatic disease is characterized by the presence of pancreatic isoenzymes.

Triglyceride and Cholesterol

Chylous pleural effusions are biochemically defined by a triglyceride level greater than 110 mg per dL and the presence of chylomicrons on a pleural fluid lipoprotein electrophoresis [12]. The usual appearance of a chylous effusion is milky, but an effusion with elevated triglycerides may also appear serous. The measurement of a triglyceride level is therefore important. Chylous effusions occur when the thoracic duct has been disrupted somewhere along its course. The most common causes are trauma and malignancy (e.g., Non–Hodgkin lymphoma) as well as in 25% of patients with lymphangioleiomyomatosis. A pseudochylous effusion appears grossly milky because of an elevated cholesterol level (>220 mg per dL), but the triglyceride level is usually normal and no chylomicrons are present. Chronic effusions, especially those associated with rheumatoid and tuberculous pleuritis are characteristically pseudochylyous.
Adenosine Deaminase

Adenosine deaminase (ADA) is abundant in lymphocytes and therefore is potentially a good marker for tuberculous pleural effusion, especially given its simpler testing methodology and lower cost as compared with measurement of pleural fluid interferon gamma level or nucleic acid polymerase chain amplification assessment [28]. Meta-analysis of ADA for the diagnosis of pleural TB has shown a sensitivity and specificity of 92% and 90%, respectively [29]. Whereas a pleural fluid ADA level <40 IU per L virtually excludes the diagnosis, levels >40 IU per L support the diagnosis and ADA levels >70 IU per L highly suggest pleural TB [24]. Because the predictive value of any test is dependent on the prevalence of disease in the specific population being tested, the use of a highly sensitive test such as the ADA in the majority of the USA (generally a low prevalence area for pleural TB) implies that the major strength of the ADA is in its negative predictive value. Multiple possible causes of false-positive ADA testing exist and include: infection, malignancy (especially lymphoma), and connective tissue diseases [29].

Cell Counts and Differential

Although pleural fluid white blood cell count and differential are never diagnostic of any disease, it would be distinctly unusual for an effusion other than one associated with bacterial pneumonia to have a white blood cell count exceeding 50,000 per μL. In an exudative pleural effusion of acute origin, polymorphonuclear leukocytes predominate early, whereas mononuclear cells predominate in chronic exudative effusions. Although pleural fluid lymphocytosis is nonspecific, severe lymphocytosis (greater than 80% of cells) is suggestive of tuberculosis or malignancy. Finally, pleural fluid eosinophilia (≥10%) is nonspecific and is most commonly associated with either blood or air in the pleural space.

A red blood cell count of 5,000 to 10,000 cells per μL must be present for a fluid to appear pinkish. Grossly bloody effusions containing more than 100,000 red blood cells per μL are most consistent with trauma, malignancy, or pulmonary infarction. To distinguish a traumatic thoracentesis from a preexisting hemothorax, several observations are helpful. First, because a preexisting hemothorax has been defibrinated, it does not form a clot on standing. Second, a hemothorax is suggested when a pleural fluid hematocrit value is 50% or more of the serum hematocrit value.
Cultures and Stains

To maximize the yield from pleural fluid cultures, anaerobic and aerobic cultures should be obtained. Because acid-fast stains may be positive in up to 20% of tuberculous effusions, they should always be performed in addition to smears using Gram’s stain. By submitting closed pleural biopsy pieces to pathology and microbiology laboratories, it is possible to diagnose up to 95% of tuberculous effusions with the combination of thoracentesis and percutaneous biopsy [7].

Cytology

Malignancies can produce pleural effusions by implantation of malignant cells on the pleura or impairment of lymphatic drainage secondary to tumor obstruction. The tumors that most commonly cause pleural effusions are lung, breast, and lymphoma. Pleural fluid cytology should be performed for an exudative effusion of unknown etiology, using at least 60 mL fluid [20,30]. If initial cytology results are negative and strong clinical suspicion exists, additional samples of fluid can increase the chance of a positive result to approximately 60% to 70%. The addition of a directed pleural biopsy (i.e., thoracoscopy) increases the yield to over 90%. In addition to malignancy, cytologic examination can definitively diagnose rheumatoid pleuritis, whose pathognomonic picture consists of slender, elongated macrophages and giant, round, multinucleated giant cells (“tadpole cells”), accompanied by an amorphous granular background material.

Chest Tube Insertion and Care
ULISES TORRES • JOSHUA R. SCURLOCK

Chest tube insertion involves placement of a sterile tube into the pleural space to evacuate air or fluid into a closed collection system to restore negative intrathoracic pressure; promote lung expansion; and prevent potentially lethal levels of pressure from developing in the thorax. Most life-threatening thoracic injuries can be treated with airway control or an appropriately placed chest tube or needle [1].

PLEURAL ANATOMY AND PHYSIOLOGY

The pleural space is a potential space that separates the visceral and parietal pleura with a thin layer of lubricating fluid. Although up to 500 mL per day of fluid may enter the pleural space, 0.1 to 0.2 mL per kg surrounds each lung in the pleural space at any given time. These two layers are lined by an extensive lymphatic network that ultimately drains into the thoracic duct via the mediastinal and intercostal lymph nodes. These lymphatics prevent the accumulation of this pleural fluid. It is estimated that this mechanism allows clearance of up to 20 mL of pleural fluid per hour per hemithorax in a 70-kg human. The elastic coil of the chest wall and lung creates a subatmospheric pressure in the space, between −5 and −10 cm H₂O, which binds the lung to the chest wall [2,3].

Drainage of the pleural space is necessary when the normal physiologic processes are disrupted by increased fluid into the space owing to alterations in hydrostatic pressures (e.g., congestive heart failure) or oncotic pressures or by changes of the parietal pleura itself (e.g., inflammatory diseases that reduce the area available for fluid resorption). A derangement in lymphatic drainage—as with lymphatic obstruction; disruption of pleural anatomy; and/or lung parenchymal anatomy due to malignancy—may also result in excess fluid accumulation.
CHEST TUBE PLACEMENT

Indications

The indications for closed intercostal drainage include a variety of disease processes in the hospital setting (Table 13.1). The procedure may be performed to palliate a chronic disease process or to relieve an acute, life-threatening process. Chest tubes also may provide a vehicle for pharmacologic interventions, as when used with antibiotic therapy; tissue plasminogen activator/fibrinolytic agents; or instillation of sclerosing agents to prevent recurrence of malignant effusions.

Pneumothorax

Accumulation of air in the pleural space is the most common indication for chest tube placement. Symptoms include tachypnea, dyspnea, and pleuritic pain, although some patients (in particular, those with a small spontaneous pneumothorax) may be asymptomatic. Physical findings include increased work of breathing, diminished breath sounds, and hyperresonance to percussion on the affected side.

Diagnosis is often confirmed by chest radiography or ultrasound (US) (details of performing this examination can be found below). The size of a pneumothorax may be estimated, but this is at best a rough approximation of a three-dimensional space using a two-dimensional view. Although the gold standard for the identification of a pneumothorax (independent of location within the thorax) has been a computed tomography (CT) scan of the chest, US identification has been shown to have the same sensitivity as that of a CT scan. Furthermore, US estimates of the extension of the pneumothorax correlate well with CT scan [4]. The sensitivity of detecting a pneumothorax with US ranges from 86% to 89%, compared to a range of 28% to 75% with a supine chest X-ray [4–6].

Immediate tube decompression is indicated for patients who are symptomatic; those who have a large or expanding pneumothorax; or those who are being mechanically ventilated. The mechanically ventilated patient is of particular concern because of acute deteriorating oxygenation that occurs with a pneumothorax in the setting of increased pleural pressure. However, a small, stable, asymptomatic pneumothorax can be followed with serial chest radiographs. Reexpansion occurs at the rate of approximately 2.2% of lung volume per day [7].

Persistent leaking of air into the pleural space with no route of escape will ultimately collapse the affected lung, flatten the diaphragm, and
eventually produce contralateral shift of the mediastinum. This is referred to as a tension pneumothorax. The combination of a collapsed lung on the affected side and the increasing pressure on the contralateral lung results in hypoxemia. The accompanying hypotension is a result of pressure on the inferior vena cava which compromises venous return. Emergency needle decompression with a 14- or 16-gauge catheter in the midclavicular line of the second intercostal space may be lifesaving while preparations for chest tube insertion are being made.

**Hemothorax**

Accumulation of blood in the pleural space can be classified as spontaneous, iatrogenic, or traumatic. Attempted thoracentesis or tube placement may result in injury to the intercostal arteries, internal mammary arteries or to the pulmonary parenchyma. Up to a third of patients with traumatic rib fractures may have an accompanying pneumothorax or hemothorax [8]. Pulmonary parenchymal bleeding from chest trauma is often self-limited owing to the low pressure of the pulmonary vascular system. However, systemic sources (intercostal, internal mammary, or subclavian arteries, aorta, or heart) may persist and become life threatening.

Indications for open thoracotomy in the setting of traumatic hemothorax include initial blood loss greater than 1,500 mL or continued blood loss exceeding 200 mL per hour for 2 to 4 hours. This decision is not based solely on the rate of continuing blood loss, but also on the patient’s physiologic status. If a hemothorax is suspected, placement of large-bore (36 to 40 French [Fr]) drainage tubes encourages evacuation of blood and helps determine the need for immediate thoracotomy [1].

**Empyema**

The management principles for pleural infection have come a long way from employing antibiotic therapy and thoracentesis to the current availability of semi-invasive and invasive procedures like video assisted thoracostomy and fibrinolytics. Use of advanced imaging like US and CT scans widens the scope of diagnosing and for treating effusions seen on a routine posteroanterior chest radiograph. Observation is usually adequate for a small (<10 mm) unseptated, free flowing effusions. Any other effusions warrant a diagnostic thoracentesis. If the aspirated fluid fulfills the criteria for being infected (pH <7.2, glucose <40 mg per dL, culture positive), a prompt plan for its drainage is recommended. Currently, large bore tube thoracostomy is the treatment option of choice for patients with empyema, but data are accumulating for treating parapneumonic effusions with small-bore intercostal drains. Early
thoracoscopy is an alternative to thrombolytics. Local expertise will dictate the choice between therapeutic thoracentesis, intrapleural fibrinolytics, and medical thoracoscopy as well as conversion to open drainage when thoracoscopy fails until randomized trials provide better evidence [9].

Chylothorax

Chylothorax is a rare condition with multiple etiologies. Pleural fluid analysis can identify this condition when clinical suspicion exists. Conservative management is generally recommended for most non-iatrogenic cases with surgery being reserved for those who have a large or persistent leak or in those who become immunologically challenged or malnourished. Conservative treatment initially involves replacing the nutrients lost in the chyle and draining large chylothoraces using chest tube insertion if necessary, to ensure complete lung expansion. Nothing by mouth or the administration of low-fat, medium-chain triglyceride enteral diet results in resolution of approximately 50% of congenital or traumatic chylothoraces. Other invasive treatments are available and are discussed in the respective sections of this book. Some of these treatments are pleurodesis; lymphangiography and embolization; and ligation of the thoracic duct thoracoscopically or by thoracotomy [10].

Pleural Effusion

Approximately 1.5 million people develop a pleural effusion in the USA each year. One of the main reasons to perform a thoracentesis (see Chapter 12) in a patient with an undiagnosed pleural effusion is to determine whether the patient has a transudative or an exudative pleural effusion. The reason to make this differentiation is that the existence of a transudative pleural effusion indicates that systemic factors such as heart failure or cirrhosis are responsible for the effusion, whereas the existence of an exudative effusion indicates that local factors are responsible for the effusion. If the patient has a transudative effusion, the systemic abnormality can be treated, and no attention needs to be diverted to the pleura. Alternatively, if an exudative effusion is present, investigations need to be directed toward the pleura to find out the cause of the local problem. Exudative effusion is present if one or more of the following conditions are met: (1) pleural fluid protein/serum protein level greater than 0.5, (2) pleural fluid lactic acid dehydrogenase (LDH)/serum LDH level greater than 0.6, or (3) pleural fluid LDH level greater than two-thirds the upper normal limit for serum LDH. The differential diagnosis list is extensive; please refer to Chapter 176 on pleural effusion for a more detailed discussion of this subject. Tube thoracostomy could be indicated
to treat and/or diagnose the etiology of the pleural effusion, but there are a lot of other modalities, like thoracentesis, pleural biopsy, bronchoscopy, thoracoscopy, and/or imaging that could be useful for the diagnosis or treatment of effusions [11].
CONTRAINDICATIONS

Published guidelines state that there are no absolute contraindications for drainage via tube thoracostomy, except when a lung is completely adherent to the chest wall throughout the hemithorax, or upon patient refusal. Relative contraindications include risks of bleeding due to coagulopathies or anticoagulation medication, and infection overlying the insertion site. Whenever possible, coagulopathies and platelet defects should be corrected prior to the procedure. Overlying cellulitis or herpes zoster infection should be avoided by choosing another puncture site. Other relative contraindications include multiple pleural adhesions, emphysematous blebs, and scarring [12].
TECHNIQUE

Chest tube insertion requires knowledge not only of the anatomy of the chest wall and intrathoracic and intra-abdominal structures, but also of general aseptic technique. The procedure should be performed or supervised only by experienced personnel, because the complications of an improperly placed tube may have immediate life-threatening results. Before tube placement, the patient must be evaluated thoroughly by physical examination and chest films to avoid insertion of the tube into a bulla or lung abscess; into the abdomen; or even into the wrong side. Particular care must be taken before and during the procedure to avoid intubation of the pulmonary parenchyma.

The necessary equipment is listed in Table 13.2. Sterile technique is mandatory whether the procedure is performed in the operating room; in the intensive care unit; in the emergency room; or on the ward. Detailed informed consent is obtained, and a time-out is performed to make sure that all the equipment is ready and available, and that the procedure is being done on the correct side and correct patient.

Careful titration of parenteral narcotics or benzodiazepines, and careful, generous administration of local anesthetic agents provide for a relatively painless procedure. Standard, large-bore drainage tubes are made from either Silastic or rubber. Silastic tubes are either right angled or straight; have multiple drainage holes; and contain a radiopaque stripe with a gap to mark the most proximal drainage hole. They are available in sizes ranging from 6 to 40 Fr, with size selection dependent on the patient population (6 to 24 Fr for infants and children) and the collection being drained (24 to 28 Fr for air; 32 to 36 Fr for pleural effusions; and 36 to 40 Fr for blood or pus). Small-caliber Silastic tubes have been increasingly employed for chest drainage, particularly after open-heart surgery, to decrease pain and allow earlier ambulation [13].

Before performing the procedure, it is important to review the steps to be taken and to ensure that all necessary equipment is available. Patient comfort and safety are paramount. There are three techniques for insertion of a thoracostomy tube. The first two direct techniques require a surgical incision and are (a) blunt dissection and (b) trocar puncture. Only the former technique is discussed here, because the latter is not commonly employed. The third technique is the percutaneous method, which can also be done at the bedside with US guidance.

1. With the patient supine and the head of the bed adjusted for comfort, the involved side is elevated slightly with the ipsilateral arm brought up over the head (Fig. 13.1). Supplemental oxygen is administered as needed. The triangle of safety is identified. This area is bordered by the anterior border of the latissimus dorsi; the lateral border of the pectoralis major muscle; a line superior to the horizontal level of the nipple; and the apex below the axilla [12].

2. The tube is usually inserted through the fourth or fifth intercostal space in the anterior axillary line. An alternative entry site (for decompression of a pneumothorax) is the second intercostal space in the midclavicular line, but for cosmetic reasons and to avoid the thick pectoral muscles, the former site is preferable in adults.

3. Under sterile conditions, the area is prepped in standard sterile fashion; and it is draped to include the nipple, which serves as a landmark, as well as the axilla. A 2- to 3-cm area is infiltrated with 1% lidocaine to raise a wheal two finger-breadths below the intercostal space to be penetrated. (This allows for a subcutaneous tunnel to be developed, through which the tube will travel, and discourages air entry into the chest following removal of the tube.)

4. A 2-cm transverse incision is made at the wheal, and additional lidocaine is administered to infiltrate the tissues through which the tube will pass, including a generous area in the intercostal space
(especially the periosteum of the ribs above and below the targeted interspace). Care should be taken to anesthetize the parietal pleura fully, because it (unlike the visceral pleura) contains somatic pain fibers. Each injection of lidocaine should be preceded by aspiration of the syringe to prevent injection into the intercostal vessels. Up to 30 to 40 mL of 1% lidocaine may be needed to achieve adequate local anesthesia.

5. To confirm the location of air or fluid, a thoracentesis is then performed at the proposed site of tube insertion. If air or fluid is not aspirated, the anatomy should be reassessed, and chest radiographs and CT scans reexamined before proceeding.

5. A short tunnel is created to the chosen intercostal space using Kelly clamps, and the intercostal muscles are bluntly divided (Fig. 13.2).

7. The closed clamp is carefully inserted through the parietal pleura, hugging the superior portion of the lower rib to prevent injury to the intercostal bundle of the rib above. The clamp is placed to a depth of less than 1 cm to prevent injury to the intrathoracic structures, and is spread open approximately 2 cm.

3. A finger is inserted into the pleural space to explore the anatomy and confirm proper location and lack of pleural symphysis. Only easily disrupted adhesions should be broken. Bluntly dissecting strong adhesions may tear the lung and initiate bleeding.

9. The end of the chest tube is grasped with the clamp and guided with the finger through the tunnel into the pleural space. Once the tip of the tube is in the pleural space, the clamp is removed, and the chest tube is advanced and positioned apically for a pneumothorax and dependently for fluid removal (Fig. 13.3A, B). All holes must be confirmed to be within the pleural space. The use of undue pressure or force to insert the tube should be avoided (Fig. 13.4A, B).

10. The location of the tube should be confirmed by observing the flow of air (seen as condensation within the tube) or fluid from the tube. It is then sutured to the skin securely to prevent slippage (Fig. 13.5). A simple suture to anchor the tube can be used, or a horizontal mattress suture can be used to allow the hole to be tied closed when the tube is removed. An occlusive petrolatum gauze dressing is applied, and the tube is connected to a drainage apparatus and securely taped to the dressing and to the patient. All connections between the patient and the drainage apparatus must also be tight and securely taped.

FIGURE 13.5 The tube is securely sutured to the skin with a 1-0 or 2-0 silk suture. This suture is left long, wrapped around the tube, and secured with tape. To seal the tunnel, the suture is tied when the tube is pulled out.
COMPLICATIONS

Chest tube insertion may be accompanied by significant complications. In one series, insertion and management of pleural tubes in patients with blunt chest trauma carried a 9% incidence of complications. Major complications requiring surgical intervention, or administration of blood products or intravenous antibiotics occurred in only four (1.7%) patients [14] (Table 13.3). The use of small-caliber, less rigid, Silastic drains has been found to be as safe and efficacious as the more rigid, conventional chest tubes [15].

CHEST TUBE MANAGEMENT AND CARE

While a chest tube is in place, the tube and drainage system must be checked at least daily for adequate functioning. Most institutions use a three-chambered system that contains a calibrated collection trap for fluid; an underwater seal unit to allow escape of air while maintaining negative pleural pressure; and a suction regulator. Suction is routinely established at 15 to 20 cm water, controlled by the height of the column in the suction regulator unit, and maintained as long as an air leak is present. The drainage system is examined daily to ensure that appropriate levels are maintained in the underwater seal and suction regulator chambers. Connections between the chest tube and the drainage system should be tightly fitted and securely taped. For continuous drainage, the chest tube and the drainage system tubing should remain free of kinks; should not be left in a dependent position; and should never be clamped. Routine milking and stripping of chest tubes is discouraged primarily in postoperative cardiac surgical patients. The data do not support routine milking and stripping, unless there is a clot in the tubing [16]. Irrigation of the tube is discouraged. Dressing changes should be performed every 2 or 3 days and as needed, making sure that no dressing with high content of petroleum-based ointment is present, because this would macerate the skin around the chest tube insertion site. Adequate pain control is mandatory to encourage coughing and ambulation to facilitate lung reexpansion.

Daily chest radiographs rarely influence chest tube management or patient care decisions, and are no longer recommended. If the patient develops clinical symptoms including shortness of breath, decreasing oxygen saturation, or subcutaneous emphysema, then radiographic evaluation is indicated [17]. A tube should never be readvanced into the pleural space, and if a tube is to be replaced, it should always be at a different site. If a pneumothorax persists, increasing the suction level may be beneficial, but an additional tube may be required if no improvement results; other etiologies should be considered after this point and further evaluation with a CT scan of the chest. Proper positioning may also be confirmed by chest CT scanning [18].
CHEST TUBE REMOVAL

Indications for removal of chest tubes include resolution of the pneumothorax or fluid accumulation in the pleural space, or both. For a pneumothorax, the drainage system is left on suction until the air leak stops. If an air leak persists, brief clamping of the chest tube can be performed to confirm that the leak is from the patient and not from the system. If, after several days, an air leak persists, placement of an additional tube may be indicated. When the leak has ceased for more than 24 to 48 hours (or if no fluctuation is seen in the underwater seal chamber), the drainage system is placed on water seal by disconnecting the wall suction, followed by a chest film several hours later. If no pneumothorax is present and no air leak appears in the system with coughing; deep breathing; and reestablishment of suction, the tube can be removed. For fluid collections, the tube can be removed when drainage is less than 200 mL per 24 hours [19], unless sclerotherapy is planned.

When the chest tube is removed, the lungs should be fully expanded, which minimizes the pleural space. This can only be achieved when the patient holds his/her breath while performing the Valsalva maneuver (i.e., trying to exhale against a closed glottis or bearing down) or at the end of expiration. US examination can confirm that lung reexpansion is complete, and chest X-ray is required only if the patient develops clinical symptoms that suggest the original problem has reoccurred [20].
RELATED SYSTEMS

Percutaneous aspiration of the pleural space to relieve a pneumothorax without an active air leak has been reported. Success rate for patients with nontraumatic PTX has ranged from 64% to 87% in adults, and 90% to 95% in children. Variation of success rates could be affected by a number of reasons including the underlying disease, the use of mechanical ventilation, or other factors [21]. Also, there have been reports of successful management of small and large pneumothoraces with small size (8.5 Fr) or pigtail catheters, connected to a portable one-way valve. Massongo et al. treated 60 patients in a prospective study, and 48 patients with large pneumothoraces were treated with small tubes and achieved a success rate of 83%. Thirty-six (60%) patients were discharged after 4 hours, and 30 patients (50%) were managed as outpatients. The 1-year recurrence rate was 17%. No severe complications were observed. The mean length of hospitalization was 2.3 ± 3.1 days. This change in management resulted in a 40% reduction in hospital stay–related costs [22].

Utility of Ultrasonography for Chest Tube Insertion and Care

Ultrasonography is superior to standard supine chest X-ray and is similar to chest CT radiography for detection of pneumothorax and pleural fluid [23,24]. Because evacuation of a pneumothorax and removal of pleural fluid are the main indications for chest tube insertion, ultrasonography has application for chest tube insertion and care.

Equipment

The ultrasonography examination is performed using a phased-array cardiac probe (3.5 to 5.0 MHz) with abdominal preset whose small footprint allows for examination between rib interspaces. A curvilinear abdominal probe may also be used. The linear high frequency probe lacks sufficient penetration to visualize deeper thoracic structures such as atelectatic lung underlying the pleural effusion, but is useful for identification of lung point while mapping out the extent of a pneumothorax.
Pleural Effusion Scanning Technique

A series of scan lines is performed over the chest in order to identify and characterize the pleural effusion, and to establish a safe site for needle insertion that avoids injury to adjacent organs. A free-flowing pleural effusion will assume a dependent position in the thorax owing to gravitational effect, so the operator examines for fluid over the lateral chest in the supine patient. A loculated pleural effusion may be located at any point in the thorax. The operator can readily locate a loculated effusion and insert a targeted chest tube for drainage of the pleural fluid [25].

Chest Tube Insertion and Care

Ultrasonography permits selection of a chest tube with the appropriate and safe angle and depth for insertion into a pleural effusion. The principles of site selection for chest tube insertion are the same as for thoracentesis (see Chapter 12 Thoracentesis). Site selection can be done rapidly in the emergency situation (thoracic trauma, tension pneumothorax on ventilatory support). Unintentional insertion of the chest tube in a subdiaphragmatic position with injury to the liver or spleen, cardiac perforation, or lung insertion are all recognized complications of chest tube insertion that can be avoided by the simple expedient of using ultrasonography for all chest tube insertions, if the capability is available [26].

Once the chest tube is in place, ultrasonography is useful for tracking adequacy of fluid drainage. Owing to the simplicity of the examination, ultrasonography is used to assess the amount of residual fluid. On occasion, a chest tube will not adequately drain the pleural effusion because of misplacement, tube blockage, or loculations. Ultrasonography can detect the adequacy of drainage; and, if the fluid is not being removed, guide decisions related to chest tube replacement or manipulation. Follow-up ultrasonography examinations take little time and are performed by the intensivist team at point of care as often as required in order to guide ongoing management of the chest tube. The decision to remove the tube may be determined with ultrasonography. At the appropriate time, the tube is clamped. Ultrasonography is used to determine if there is significant fluid reaccumulation. If not, the chest tube may be removed. It is feasible to use ultrasonography as the main imaging modality for management of pleural fluid removal.

Pneumothorax
Scanning Technique

A series of scan lines are performed over the chest in order to locate the pneumothorax and to establish a safe site for chest tube insertion that avoids injury to adjacent organs. In the supine patient, air in the pleural space will distribute anteriorly; so the examination for pneumothorax is concentrated over the anterior and lateral chest. Not all pneumothoraces assume a typical distribution. A loculated pneumothorax is always a possibility. This may occur with pleural adhesions that cannot be detected with ultrasonography. Excepting the emergency situation where an acute life-threatening tension pneumothorax is under consideration, ultrasonography is integrated with the review of the chest radiography and chest CT in order to rule out the presence of a loculated pneumothorax before targeted insertion of a chest tube.

Chest Tube Insertion and Care

The presence of lung sliding, lung pulse, or B lines rules out pneumothorax at the site of the examination (See Chapter 11 Lung Ultrasonography). Multiple intercostal spaces can be examined in a short period time in order to exclude pneumothorax with a high level of certainty in the patient. The absence of lung sliding is characteristic but not diagnostic for a pneumothorax. Identification of a lung point verifies the presence of pneumothorax [27] and allows the operator to map out the lateral extent of the pneumothorax. This is helpful in determining a safe site for chest tube insertion [28]. Most pneumothoraces are not complete (i.e., they result in partial lung atelectasis). The chest tube needs to be inserted into the pneumothorax space. Insertion where lung is still inflated against the chest wall may result in placement of the chest tube into the lung. The operator inserts the device into the area of the chest that lacks lung sliding and that is demarcated laterally by the lung point.

Once the tube is inserted, adequacy of lung inflation is determined by the return of lung sliding, lung pulse, and/or B lines. The timing of chest tube removal following chest tube insertion for pneumothorax is guided with ultrasonography as follows [29–31]:

1. The lung is determined to be fully inflated by ultrasonography, and there is no air leak from the chest tube.
2. The team determines that there are no clinical factors that require continued chest tube use.
3. The tube is clamped, and the chest is examined with ultrasonography immediately for evidence of reaccumulation of the pneumothorax.
4. Over the course of several hours, the chest is examined with ultrasonography for evidence of delayed pneumothorax accumulation.

5. If the lung remains inflated by ultrasonography criteria, the tube may be removed.

INTRODUCTION

The era of modern resuscitation can be most directly traced to a report of electrical reversal of ventricular fibrillation (VF) by externally applied electrodes described in 1956 by Zoll et al. [1]. This ability to reverse a fatal arrhythmia without opening the chest challenged the medical community to develop a method of sustaining adequate ventilation and circulation long enough to bring the electric defibrillator to the patient’s aid. By 1958, adequate rescue ventilation became possible with the development of the mouth-to-mouth technique described by Safar et al. [2] and Elam et al. [3]. In 1960, Kouwenhoven et al. [4] described “closed chest cardiac massage,” thus introducing the modern era of cardiopulmonary resuscitation (CPR). The simplicity of this technique—“all that is needed are two hands”—has led to its widespread dissemination. The interaction of this technique of sternal compression with mouth-to-mouth ventilation was developed as basic CPR. The first national conference on CPR was sponsored by the National Academy of Sciences in 1966 [5]. Instructions in CPR for both professionals and the public soon followed through community programs in basic life support (BLS) and advanced cardiac life support (ACLS) [6] and have been updated periodically.

For individuals with adequately preserved cardiopulmonary and neurologic systems, the cessation of breathing and cardiac contraction may be reversed if CPR and definitive care are quickly available. The short period during which the loss of vital signs may be reversed is often referred to as clinical death. If ventilation and circulation are not restored before irreversible damage to vital structures occurs, then
irreversible death occurs. This is referred to as *biologic death*. In difficult circumstances, the best single criterion (medical and legal) for the ultimate death of the functioning integrated human individual (i.e., the person) is brain death [7,8]. By this criterion, we can make decisions as to the appropriateness of continuing “life-sustaining” techniques.
EFFICACY

High quality CPR produces a cardiac output of 25% to 33% of normal [9,10]. The benefit of rapid initiation of CPR has been demonstrated in numerous studies [11–14]. A large registry that recorded outcomes of over 70,000 cardiac arrest patients noted that survival from sudden cardiac arrest has slowly improved, with 8.3% of patients surviving to hospital discharge [15]. Survival with a good neurologic outcome, usually defined as being no worse than moderate disability, has also improved. In a large randomized controlled trial comparing different target temperatures after cardiac arrest of patients who survived to hospital admission and maintained a pulse for 20 minutes, survival at 6 months was approximately 50%, and the majority of survivors had good neurologic outcomes [16]. Data from prehospital care systems in Seattle showed that 43% of patients found in VF were discharged from the hospital if CPR (i.e., BLS) was applied within 4 minutes and defibrillation (i.e., ACLS) within 8 minutes. If the onset of CPR was delayed, or if the time to defibrillation was longer than 10 minutes, the probability was greater that the patient was in asystole or in fine VF that converted to asystole. Survival decreases as each minute passes without return of spontaneous circulation (ROSC), and a compression rate of 85 to 100 is associated with better survival than higher or lower rates [17]. Early access to defibrillation via the use of automated external defibrillators (AEDs) also improves survival [18].

Even though patients experiencing cardiac arrest in the hospital can be expected to receive CPR and definitive therapy well within the 4- and 8-minute time frames, the outcomes of in-hospital cardiac arrests are poor. The largest report of survival after in-hospital cardiac arrest recorded that 15% of victims survive to hospital discharge [19]. With the wide availability of AEDs in the community, two large registry studies have suggested that survival with intact neurologic function may be improving. In a study from Japan, survival with good neurologic function increased from 3.3% to 8.2% from 2005 to 2012 [20]. In a statewide study from North Carolina, survival with a favorable neurologic outcome increased from 7.1% to 9.7% from 2010 to 2013 [21]. In both of these studies bystander defibrillation was associated with a substantial increase in survival with intact neurologic function.

Researchers continue to evaluate new approaches and techniques, and further refinements in the delivery of CPR can be expected. Although research into improved CPR techniques and devices should be encouraged, research in this field is difficult. Animal models vary, and animal data may not be valid in humans. Before new CPR techniques can
be adopted, they must have been demonstrated, ideally in humans, to improve either survival or neurologic outcomes.

Any significant improvement in CPR technique would seem to require an understanding of the mechanism by which blood flows during CPR. While there is no conclusive evidence as to the mechanism of blood flow during CPR, the two main theories are the cardiac compression (or pump) theory and the thoracic pump theory [22].

In 1960, when Kouwenhoven et al. [4] reported on the efficacy of closed chest cardiac massage, most researchers accepted the theory that blood is propelled by compressing the heart trapped between the sternum and the vertebral columns—the cardiac compression theory. According to this theory, during sternal compression, intraventricular pressures rise higher than the pressures elsewhere in the chest. With each sternal compression, semilunar valves would be expected to open and atrioventricular (AV) valves to close. With sternal release, pressure in the ventricles would be expected to fall and AV valves would open, allowing the heart to fill from the lungs and systemic veins.

In contrast to the cardiac compression theory, the thoracic pump theory proposes that the propulsion of blood during sternal compression is due to increased intrathoracic pressure [23,24]. According to this theory, the heart serves as a conduit only during CPR. Forward flow is generated by a pressure gradient between intrathoracic and extrathoracic vascular structures. Flow to the arterial side is favored by functional venous valves and greater compressibility of veins, compared to arteries, at their exit points from the thorax. Studies using pressure measurements [13] and angiography [23] support this hypothesis, as do most echocardiographic studies [25]. It is noteworthy that the dominating mechanism may vary among individual patients, with one large review suggesting that the cardiac pump predominates in children, whereas the thoracic pump is more important in adults [22].
Several experimental and alternative techniques of CPR have been proposed, though none are recommended for general use according to the American Heart Association (AHA) 2010 guidelines [10]. High frequency chest compressions, such as at a rate >120 per minute, may improve hemodynamics, but have not improved clinical outcomes. Open chest CPR, in which the heart is manually compressed via a left thoracotomy incision, may have a role in select cases of penetrating trauma or in the early postoperative period after cardiothoracic surgery. This technique should not be attempted unless adequate facilities and trained personnel are available. Interposed abdominal compression CPR was developed by Ralston et al. [26] and Babbs et al. [27]. This technique includes manual compression of the abdomen by an extra rescuer during the relaxation phase of chest compression. The mid-abdomen is compressed at a point halfway between the xiphoid process and the umbilicus with a force of approximately 100 mm Hg of external pressure. This pressure is estimated to be equivalent to that required to palpate the aortic pulse in a subject with a normal pulse. Two randomized clinical trials have demonstrated a statistically significant improvement in outcome measures for in-hospital cardiac arrest [28,29] but no improvement has been shown for out-of-hospital arrest [30]. On the basis of these findings, interposed abdominal compression CPR is recommended as an option for in-hospital cardiac arrest when sufficient trained personnel are available [10]. However, the safety and efficacy of interposed abdominal compression CPR for patients with recent abdominal surgery, pregnancy, or aortic aneurysm has not been studied.

Several mechanical assist devices have been designed to provide or augment compressions (CPR vests, powered piston devices, active decompression devices using a suction cup applied to the anterior chest). However, none of these have been clearly shown to improve outcomes, and none are recommended by the AHA 2010 guidelines [10]. The use of an impedance threshold device is an option according to the AHA guidelines. These devices limit air entry into the lungs during decompression, allowing the resulting negative pressure to induce more effectively venous return. They are typically used with an advanced airway (supraglottic or endotracheal) [10]. One review identified an improvement in survival to hospital admission, but no improvement in survival to discharge or in neurologic outcome with the use of an impedance threshold device in out-of-hospital cardiac arrest [31].
The fear provoked by the spread of human immunodeficiency virus (HIV) may lead to excessive caution when dealing with strangers. Fear of acquiring infection during the performance of CPR, specifically mouth-to-mouth ventilation, can best be counteracted by continued education. Saliva has not been implicated in the transmission of HIV even after bites, percutaneous inoculation, or contamination of open wounds with saliva from HIV-infected patients [32–34]. In fact, neither hepatitis B or C nor HIV have been reported to have been acquired via CPR, excepting needle sticks and prolonged exposure of damaged skin to blood (not saliva). Infections thought to have been transmitted by CPR include Mycobacterium tuberculosis, meningococcus, herpes simplex, Shigella, Streptococcus pyogenes, Salmonella, and Neisseria gonorrhoeae [34].

Implications for Rescuers with Known or Potential Infection

Potential rescuers who know or are highly suspicious that they are infected with a serious pathogenic organism should not perform mouth-to-mouth ventilation if another rescuer is available who is less likely to be infectious or if the circumstances allow for any other immediate and effective method of ventilation, such as using mechanical ventilation devices. Compression-only CPR is a reasonable and safe alternative.

Health care professionals with known or potential infections should have ready access to mechanical ventilation devices. Bag–valve–mask devices should be available as initial ventilation equipment, and early endotracheal intubation should be encouraged when possible. Masks with one-way valves and plastic mouth and nose covers with filtered openings are available and provide some protection from transfer of oral fluids and aerosols. S-shaped mouthpieces, masks without one-way valves, and handkerchiefs provide little, if any, barrier protection and should not be considered for routine use. With these guidelines in mind, health care professionals are reminded that they have a special moral and ethical, and in some instances legal, obligation to provide CPR, especially in the setting of their occupational duties.
STANDARD PROCEDURES AND TEAM EFFORT

The distinctive function of the intensive care unit (ICU) is to serve as a locus of concentrated expertise in medical and nursing care, life-sustaining technologies, and treatment of complex multiorgan system derangements. Historically, it was the development of effective treatment for otherwise rapidly fatal arrhythmias during acute myocardial infarction that impelled the medical community to establish ICUs \[35\]. Rapid response by medical personnel has been facilitated by constant professional attendance and the development of widely accepted guidelines for resuscitation. Each member of the professional team is expected to respond in accordance with these guidelines.

Avoiding the need for CPR and ACLS by early intervention is a goal of rapid response teams (RRT). RRT, also called medical evaluation teams (MET), have been consistently shown to decrease hospital cardiorespiratory arrest rates \[36\]. Some studies have found a decrease in hospital mortality with the use of RRT, though this has not been found in all studies. How RRT can best be organized and implemented, as well as which hospitals benefit most, is yet to be determined \[37\].

The skills necessary to perform adequately during a cardiac or respiratory arrest and to interface smoothly with ACLS techniques cannot be mastered by reading texts and manuals alone. CPR courses taught according to AHA guidelines allow hands-on experience that approximates the real situation and tests the psychomotor skills needed in an emergency. All those who engage in patient care should be trained in BLS techniques. Those whose duties require a higher level of performance should be trained in ACLS as well. As these skills deteriorate with disuse, they need to be maintained. It is worth noting that there is no “certification” in BLS or ACLS. Issuance of a “card” is neither a license to perform these techniques nor a guarantee of skill, but simply an acknowledgment that an individual attended a specific course and passed the required tests. If employers or government agencies require such a card of their health workers, it is by their own mandate.

The ensuing discussion of BLS and ACLS techniques follows the recommendations and guidelines established by the AHA \[38\].
BASIC LIFE SUPPORT FOR ADULTS WITH AN UNOBSSTRUCTED AIRWAY

BLS is meant to support the circulation and respiration of those who have experienced cardiac or respiratory arrest. After recognizing and ascertaining its need, definitive help is summoned without delay and CPR is initiated. A major focus of the 2010 guidelines is on the supremacy of effective compressions, with limited interruptions. The importance of early defibrillation is also stressed.

Respiratory Arrest

Respiratory arrest may result from airway obstruction, near-drowning, stroke, smoke inhalation, drug overdose, electrocution, or physical trauma. In the ICU, infections, pulmonary congestion, respiratory distress syndrome, and mucus plugs are frequent causes of primary respiratory arrests. The heart usually continues to circulate blood for several minutes, and the residual oxygen in the lungs and blood may keep the brain viable. Early intervention by opening the airway and providing ventilation may prevent cardiac arrest and may be all that is required to restore effective respiration. In the intubated patient, careful suctioning of the airway and attention to the ventilator settings are required. Lay rescuers should not check for a pulse, but if a health care professional ascertains that the patient does have a pulse, then rescue breaths should be performed at a rate of one breath every 5 to 6 seconds while arranging for more definitive airway management.

Cardiac Arrest

Cardiac arrest results in rapid depletion of oxygen in vital organs. After 6 minutes, brain damage is expected to occur, except in cases of hypothermia (e.g., near-drowning in cold water). Therefore, early bystander CPR (within 4 minutes) and rapid ACLS with attempted defibrillation (within 8 minutes) are essential in improving survival and neurologic recovery rates [39].

The sequence of steps in CPR may be summarized as the CABs of CPR: circulation, airway, and breathing. This mnemonic is useful for teaching the public, but it should be remembered that each step is preceded by assessment of the need for intervention: before starting compressions, the rescuer determines unresponsiveness; before breathing, the rescuer determines breathlessness (Table 14.1).

Assessment and Determination of Unresponsiveness and Alerting of Emergency Medical Services

A person who has undergone cardiac arrest may be found in an apparently unconscious state (i.e., an unwitnessed arrest) or may be observed to suddenly lapse into apparent unconsciousness (i.e., a witnessed arrest). In either case, the rescuer must react promptly to assess the person’s responsiveness by attempting to wake and communicate with the person by tapping or gently shaking and shouting. The rescuer should summon nearby staff for help. If no other person is immediately available, the rescuer should activate emergency medical services (EMS) or call the hospital emergency line for the resuscitation team to respond (“code blue”).

In the ICU, nearly all arrests should be witnessed. Early recognition of cardiac and respiratory arrests is facilitated by electronic and video monitoring. Unfortunately, it is quite possible for a patient to become lost behind this profusion of electronic signals, the dependability of which varies widely. For several precious minutes, a heart with pulseless electric activity (PEA) continues to provide a comforting electronic signal, while the brain suffers hypoxic damage. A high frequency of false alarms and an overwhelming volume of alarms may dangerously raise the threshold of awareness and prolong the response time of the ICU team. [40]. The overall efficacy of the monitoring devices depends highly on meticulous skin preparation and care of electrodes, transducers, pressure cables, as well as caregiver response to alarms.

Sudden apparent loss of consciousness, occasionally with seizures, may be the first signal of arrest and requires prompt reaction. After determining unresponsiveness, the pulse is assessed by a health care provider for no more than 10 seconds. If the carotid pulse cannot definitely be palpated in 5 to 10 seconds and a defibrillator is not immediately available, CPR should be begun. Compressions should be performed at a rate of 100 per minute, compressing the chest 2 inches with each repetition and allowing the chest to recoil fully. Interruptions to compressions should only be allowed for essential interventions, such as
as intubation or defibrillation. Note that, in the 2010 guidelines, compressions should be started before assessing breathing.

Opening the Airway and Determining Breathlessness

After establishing unresponsiveness, activating EMS, and delivering 30 compressions and positioning the individual on his or her back, the next step is to open the airway and check for spontaneous breathing (see Chapter 8). In a monitored arrest with VF or tachycardia, this step is taken after initial attempts to defibrillate. Meticulous attention to establishing an airway and supplying adequate ventilation is essential to any further resuscitative effort. The team leader must carefully monitor the adequacy of ventilation, as well as direct the resuscitative effort. The leadership role is best accomplished if the leader does not directly perform procedures.

The head tilt–chin lift maneuver is usually successful in opening the airway. The head is tilted backward by a hand placed on the forehead. The fingers of the other hand are positioned under the mandible and the chin is lifted upward. The teeth are almost approximated, but the mouth is not allowed to close. Because considerable cervical hyperextension occurs, this method should be avoided in patients with cervical injuries or suspected cervical injuries. The jaw-thrust maneuver provides the safest initial approach to opening the airway of a patient with a cervical spine injury; it usually allows excellent airway opening with a minimum of cervical extension. The angles of the mandible are grasped using both hands and lifting upward, thus tilting the head gently backward.

Rescue Breathing

If spontaneous breathing is absent, rescue breathing with an airway–mask–bag unit must be initiated (see Chapter 8). If equipment is immediately available and the rescuer is trained, intubation and ventilatory adjuncts should be used initially. Each breath should be delivered during 1 second, allowing the patient’s lungs to deflate between breaths. A rate of 10 to 12 breaths per minute is maintained for as long as necessary, with tidal volumes of approximately 600 mL. Delivering the breath during 1 second helps to prevent gastric insufflation compared with faster delivery. Melker et al. [41] demonstrated airway pressures well in excess of those required to open the lower esophageal sphincter when quick breaths are used to ventilate patients. If the patient wears
dentures, they are usually best left in place to assist in forming an adequate seal.

If air cannot be passed into the patient’s lungs, another attempt at opening the airway should be made. The jaw-thrust maneuver may be necessary. If subsequent attempts at ventilation are still unsuccessful, the patient should be considered to have an obstructed airway and attempts should be made to dislodge a potential foreign body obstruction.

**Chest Compressions**

Artificial circulation depends on adequate chest compression through sternal depression. Recent recommendations for CPR are to push hard and push fast at a rate of 100 compressions per minute, allow full chest recoil, and minimize interruptions in chest compressions [42]. The safest manner of depressing the sternum is with the heel of the rescuer’s hand at the nipple line, with the fingers kept off the rib cage. It is usually most effective to cover the heel of one hand with the heel of the other, the heels being parallel to the long axis of the sternum. If the rescuer’s hands are placed either too high or too low on the sternum, or if the fingers are allowed to lie flat against the rib cage, broken ribs and organ laceration can result. Although it is important to allow the chest to recoil to its normal position after each compression, it is not advisable to lift the hands from the chest or change their position.

The rescuer’s elbows should be kept locked and the arms straight, with the shoulders directly over the patient’s sternum. This position allows the rescuer’s upper body to provide a perpendicularly directed force for sternal depression. The sternum is depressed 2.0 inch (4 to 5 cm) at a rate of approximately 100 compressions per minute. In large patients, a slightly greater depth of sternal compression may be needed to generate a palpable carotid or femoral pulse. At the end of each compression, pressure is released and the sternum is allowed to return to its normal position. Equal time should be allotted to compression and relaxation with smooth movements, avoiding jerking or bouncing the sternum. Ventilation and sternal compression should not be interrupted except under special circumstances. Warranted interruptions include execution of ACLS procedures (e.g., endotracheal intubation and placement of central venous lines) or an absolute need to move the patient. Even in these limited circumstances, interruption of CPR should be minimized. In a retrospective analysis of VF patients, interruption of CPR was associated with a decreased probability of conversion of VF to another rhythm [43].
New data suggest that chest compression-only CPR is as effective as standard CPR (chest compression plus rescue breathing) for out-of-hospital arrest [44,45]. Subgroup analysis in one study suggested a trend for increased survival to hospital discharge for chest compression-only CPR if the cause of the arrest was cardiac in origin or the rhythm was shockable [44]. For lay persons, the 2010 AHA guideline supports compression-only CPR.

Two-Rescuer CPR

The combination of artificial ventilation and circulation can be delivered more efficiently and with less fatigue by two rescuers. One rescuer, positioned at the patient’s side, performs sternal compressions, while the other, positioned at the patient’s head, maintains an open airway and performs ventilation. This technique should be mastered by all health care workers called on to perform CPR. Lay people have not been routinely taught this method in the interest of improving retention of basic skills. The compression rate for two-rescuer CPR, as for one-rescuer CPR, is approximately 100 compressions per minute. The recommendation of the compression-to-ventilation ratio is 30 to 2. The only exception to this recommendation is when two health care workers are providing CPR to a child or infant (except newborns); in this instance, a 15 to 2 compression-to-ventilation ratio should be used [42]. When the rescuer performing compressions is tired, the two rescuers should switch responsibilities with the minimum possible delay.

Complications of BLS Procedures

Proper application of CPR should minimize serious complications, but serious risks are inherent in BLS procedures and should be accepted in the context of cardiac arrest. Awareness of these potential complications is important to the postresuscitative care of the arrest patient.

Gastric distention and regurgitation are common complications of artificial ventilation without endotracheal intubation. These complications are more likely to occur when ventilation pressures exceed the opening pressure of the lower esophageal sphincter. In mask ventilation, 1 second should be allowed for air delivery. Although an esophageal obturator airway may decrease the threat of distention and regurgitation during its use, the risk is increased at the time of its removal. To obviate this risk, the trachea should be intubated and protected with an inflated cuff before the esophageal cuff is deflated and the esophageal obturator removed.

Complications of sternal compression and manual thrusts include rib and sternal fractures, costochondral separation, flail chest, pneumothorax, hemothorax, hemopericardium, subcutaneous
emphysema, mediastinal emphysema, pulmonary contusions, bone marrow and fat embolism, and lacerations of the esophagus, stomach, inferior vena cava, liver, or spleen [46]. Although rib fractures are common during CPR, especially in the elderly, no serious sequelae are likely unless tension pneumothorax occurs and is not recognized. The more serious complications are unlikely to occur if proper hand position is maintained and exaggerated depth of sternal compression is avoided. Overzealous or repeated abdominal or chest thrusts for relief of airway obstruction are more likely to cause fractures or lacerations. For this reason, abdominal thrust is not recommended for the infant younger than 1 year.

Monitoring the Effectiveness of Basic Life Support

The effectiveness of rescue effort is assessed regularly by the ventilating rescuer, who notes the chest motion and the escape of expired air. Unintentional hyperventilation is frequent during CPR, with studies in clinical situations showing that patients are commonly ventilated at a rate of 18 to 30, far faster than recommended [47]. The adequacy of circulation is assessed by noting an adequate carotid pulse with sternal compressions.

Pupillary response, if present, is a good indicator of cerebral circulation. However, fixed and dilated pupils should not be accepted as evidence of irreversible or biologic death. Ocular diseases, such as cataracts, and a variety of drugs (e.g., atropine and ganglion-blocking agents) interfere with the pupillary light reflex. The decision to cease BLS should be made only by the physician in charge of the resuscitation effort; this decision should not be made until it is obvious that the patient’s cardiovascular system will not respond with ROSC to adequate administration of ACLS, including electric and pharmacologic interventions. Remediable problems such as airway obstruction, severe hypovolemia, and pericardial tamponade should also have been reasonably excluded by careful attention to ACLS protocols. Published guidelines suggest that BLS can be stopped if all of the following are present: the event was not witnessed by EMS personnel, no AED has been used, and there is no ROSC in the prehospital setting [48] (Table 14.2).

Note: Maneuvers used by only health care providers are indicated by “HCP.” CPR, cardiopulmonary resuscitation; AED, automatic external defibrillator.
PEDIATRIC RESUSCITATION

The 2010 AHA guidelines for pediatric CPR are similar to the adult guidelines, with the exception that when performing two-person CPR, a ratio of 15 compressions to two breaths should be used. The rate of compressions remains 100 per minute, and the depth of compressions from 1.5 inches or infants to 2 inches for children; another way to gauge compression depth is to target one-third of the anteroposterior (AP) size of the patient [49].
OBSTRUCTED AIRWAY

An unconscious patient can experience airway obstruction when the tongue falls backward into the pharynx. Alternatively, the epiglottis may block the airway when the pharyngeal muscles are lax. In the sedated or ill patient, regurgitation of stomach contents into the pharynx is a frequent cause of respiratory arrest. Blood clots from head and facial injuries are another source of pharyngeal and upper airway obstruction. Even otherwise healthy people may have foreign body obstruction from poorly chewed food, large wads of gum, and so forth. The combination of attempting to swallow inadequately chewed food, drinking alcohol, and laughing is particularly conducive to pharyngeal obstruction. Children’s smaller airways are likely to obstruct with small nuts or candies. Children are also prone to airway obstruction by placing toys or objects such as marbles or beads in their mouths.

Patients who experience partial obstruction with reasonable gas exchange should be encouraged to continue breathing efforts with attempts at coughing. A patient whose obstruction is so severe that air exchange is obviously markedly impaired (cyanosis with lapsing consciousness) should be treated as having complete obstruction.

Patients who experience complete obstruction may still be conscious, but are unable to cough or vocalize. A subdiaphragmatic abdominal thrust may force air from the lungs in sufficient quantity to expel a foreign body from the airway [50].

If the person is still standing, the rescuer stands behind the person and wraps his or her arms around the person’s waist. The fist of one hand is placed with the thumb side against the person’s abdomen in the midline, slightly above the umbilicus and well below the xiphoid process. The fist is grasped with the other hand and quickly thrust inward and upward. It may be necessary to repeat the thrust six to ten times to clear the airway. Each thrust should be a separate and distinct movement.

If the patient is responsive and lying down, he or she should be positioned face up in the supine position. The rescuer kneels beside or astride the person’s thighs and places the heel of one hand against the person’s abdomen, slightly above the umbilicus and well below the xiphoid process. The other hand is placed directly on top of the first and pressed inward and upward with a quick forceful thrust. If the patient is unresponsive, CPR should be initiated.
If attempted rescue breathing in an arrested patient fails to move air into the lungs, an obstructed airway must be presumed to be present. It may simply be due to the tongue or epiglottis, rather than a foreign body. If the airway remains closed after repositioning the head, other maneuvers to open the airway, including the jaw-thrust and tongue-jaw lift, must be used. Chest thrusts may be substituted for abdominal thrusts in patients in advanced stages of pregnancy, in patients with severe ascites, or in the markedly obese. The fist is placed in midsternum for the erect and conscious patient. For the supine patient, the hand is positioned on the lower sternum, as for external cardiac compression. Each thrust is delivered slowly and distinctly.

If attempts at dislodging a foreign body or relieving airway obstruction fail, special advanced procedures are necessary to provide oxygenation until direct visualization, intubation, or cricothyroidotomy is performed (Chapter 8).
ADVANCED CARDIAC LIFE SUPPORT IN ADULTS

The use of adjunctive equipment, more specialized techniques, and pharmacologic and electric therapy in the treatment of a person who has experienced cardiac or respiratory arrest is generally referred to as ACLS. As with any skill, excellence requires both training and practice. An improvement in survival after in-hospital cardiac arrest has been demonstrated after medical house officers were trained in ACLS [51]. An in-depth discussion is available in the ACLS text published by the AHA.

The focus of the following sections is on the techniques and medications used in the initial resuscitative efforts. The demarcation from therapies more commonly reserved for the ICU is often indistinct; indeed, it is expected to vary with the experience of the team and the degree of physician supervision. In general, most ACLS measures should be applied by trained personnel operating within an EMS system in the community, in transport, or in the hospital setting.

Airway and Ventilatory Support

Oxygenation and optimal ventilation are prerequisites for successful resuscitation. Supplemental oxygen should be administered as soon as it becomes available, beginning with 100%. In the postresuscitation period, the amount of administered oxygen may be decreased as guided by oxygen saturation.

Emergency ventilation commonly begins with the combined use of a mask and oral airway. The AHA guideline continues to recommend ventilation during CPR when performed by ACLS providers, but ventilation should neither interrupt early compressions nor delay defibrillation. Mouth-to-mask ventilation is very effective as long as an adequate seal is maintained between the mask and the face; this method is recommended for single-rescuer ACLS. Most masks are best fitted by flaring the top and molding it over the bridge of the nose. The inflated rim is then carefully molded to the cheeks as the mask is allowed to recoil. Relatively firm pressure is required to maintain the seal. Masks with one-way valves also provide a measure of isolation from the patient’s saliva and breath aerosol. Bag–valve–mask ventilation requires strong
hands and a self-inflating bag. The bag should be connected to a gas reservoir and to oxygen so that 100% oxygen delivery can be approximated. It cannot be overemphasized that the success of this method depends on airway patency and an adequate seal between the mask and the face. Equally important is adequate compression of the bag to deliver the required tidal volume of approximately 600 mL. It is advisable that everyone who uses this technique practice on a manikin to assess the adequacy of the method in his or her hands. Many people will discover that their hands are not large enough or strong enough to deliver 600 mL air. Some may have to squeeze the bag between their elbow and chest wall to supply adequate ventilation. If two people are available to ventilate, one should secure the mask while the other uses both hands to attend to the bag.

Cricoid pressure is not recommended during bag mask ventilation. Nasopharyngeal and oropharyngeal airways are both reasonable options to improve airway patency prior to an advanced airway. Nasopharyngeal airways may cause bleeding, and should be avoided in patients with basilar skull fractures.

The mask should include the following features:

- The use of transparent material, which allows the rescuer to assess lip color and to observe vomitus, mucus, or other obstructing material in the patient’s airway.
- A cushioned rim around the mask’s perimeter to conform to the patient’s face and to facilitate a tight seal.
- A standard 15- to 22-mm connector, which allows the use of additional airway equipment.
- A comfortable fit to the rescuer’s hand.
- An oxygen insufflation inlet, which allows oxygen supplementation during mouth-to-mask ventilation.
- A one-way valve, which allows some protection during mouth-to-mask ventilation.
- Availability in appropriate sizes and shapes, for various-sized faces. Most adults will be accommodated by a standard medium-sized (no. 4) oval-shaped mask.

Ventilating bags must be designed to include the following features:

- A self-refilling bag, which allows operation independent of a fresh gas source.
A fresh gas inlet, which allows ambient air or supplemental oxygen to flow into the reservoir bag through a valve inlet. A nipple for oxygen connection, located near the gas inlet valve. An oxygen reservoir bag. Availability in pediatric and adult sizes.

A nonrebreathing valve directing flow to the patient during inhalation and to the atmosphere during exhalation. The valve casing should be transparent to allow visual inspection of its function. A pop-off feature is often present to prevent high airway pressures; however, such valves should have provision to override the pop-off feature because higher airway pressures are sometimes required to ventilate lungs with unusually high resistances, especially in children.

Reservoir tubing that can be attached to the fresh gas inlet valve which allows oxygen to refill the reservoir bag during exhalation. Such a reservoir allows delivered oxygen to approach 100%; without it, the self-refilling bag can deliver only 40% to 50% oxygen.

For patients undergoing prolonged arrest, or for whom mask ventilation is unsuccessful, placement of an advanced airway should be performed. Precisely when to perform airway placement during resuscitation is not well defined, but it should be delayed at least until the first round of CPR and defibrillation in arrests felt to be primarily cardiac (rather than respiratory) in origin. In view of minimizing interruptions to compressions, it should be noted that supraglottic airways can be placed without stopping compressions.

Selection of which advanced airway device to use depends on the situation and especially upon the skill of the providers present. Advanced airways include supraglottic devices and endotracheal devices. Supraglottic devices do not require visualization of the glottis and are technically less demanding to place. Esophageal tracheal tubes (Combitube) allow blind placement and effective ventilation at rates similar to those achieved with endotracheal tube placement by inexperienced providers [52]. The laryngeal tube, which is designed to be placed in the esophagus and is inflated via a single port, is also an option.

The laryngeal mask airway (LMA) has been effective for maintaining airway patency during anesthesia since 1988 and is an acceptable alternative to mask ventilation during ACLS. The LMA provides a more stable and consistent means of ventilation than bag mask ventilation. Current research concludes that regurgitation is less common with LMA than with the bag mask, and although it cannot provide complete protection from aspiration, it is less frequent when used as the first-line airway device [53,54]. Multiple studies have documented the advantages
of LMA for its relative ease with insertion and ease of use by a variety of personnel: nurses, medical students, respiratory therapists, and EMS, many with little prior experience using the device. Studies have shown that inexperienced personnel achieved an 80% to 94% success rate on first placement attempts and achieved 98% and 94% on subsequent attempts of adult and pediatric cases, respectively [54]. The LMA provides adequate and effective ventilation when measured against endotracheal intubation [55]. Additionally, less equipment and training are needed to insert the device successfully. It may also have advantages over the endotracheal tube when patient airway access is obstructed, when the patient has an unstable neck injury, or when suitable positioning of the patient for endotracheal intubation is unattainable. LMA insertion has been successful when attempts at endotracheal intubation by experts were unsuccessful [55]. Endotracheal tubes can be fiberoptically inserted through an established LMA.

Relative contraindications for LMA use include the patient with an increased risk of aspiration pneumonitis. Examples of such situations include morbid obesity, pregnancy, recent food ingestion, gastrointestinal obstruction, and hiatal hernia. Despite these considerations, oxygenation and ventilation during cardiac arrest receive top priority and the LMA should be used if it is the fastest and most efficient means of providing airway patency.

When an endotracheal tube is chosen during ACLS, interruptions to compressions should be limited to not more than 10 seconds if possible. Once placed, correct endotracheal tube placement must be verified as unrecognized misplacement or displacement is common. One study of 108 patients found a 25% rate of misplaced endotracheal tubes on emergency room arrival [56]. Providers should confirm correct placement of the endotracheal tube by examination of the chest as well as capnography and ultrasonography. Continuous capnography is recommended as this allows rapid recognition of endotracheal tube displacement during transport. Alternatives to capnography include end-tidal CO$_2$ detectors and esophageal detector devices. When an end-tidal CO$_2$ detector is positive (CO$_2$ detected), the provider can be confident the tube is endotracheal. False-negative end-tidal CO$_2$ detectors (i.e., no color change but the tube is endotracheal) may occur, most commonly due to low blood flow during CPR. If CO$_2$ is not detected using an end-tidal CO$_2$ detector, laryngoscopy or an esophageal detection device (EDD) should be used to confirm placement, though the evidence supporting the use of
EDDs is limited. While not discussed in the AHA guidelines, if attempts at relieving an obstructed airway have failed, several advanced techniques may be used to secure the airway until intubation or tracheostomy is successfully performed. Transtracheal catheter ventilation is performed by inserting a catheter over a needle through the cricothyroid membrane. The needle is removed and intermittent jet ventilation initiated (see Chapter 8). In cricothyrotyotomy, an opening is made in the cricothyroid membrane with a scalpel (see Chapters 8, 9). Tracheostomy, if still necessary, is best performed in the operating room by a skilled surgeon after the airway has already been secured by one of the aforementioned techniques.

After placement of an advanced airway, compressions should not be interrupted and should be continued at a rate of 100 per minute with respirations delivered at a rate of 8 to 10 per minute. Hyperventilation should be consciously avoided as hyperventilation during resuscitation is common and may be detrimental [47].

Circulatory Support

Chest compression should not be unduly interrupted while adjunctive procedures are instituted. The rescuer coordinating the resuscitation effort must ensure that adequate pulses are generated by the compressor. The carotid or femoral pulse should be evaluated every few minutes, and while not well studied, the palpation of a carotid pulse during CPR is often used to help assess the adequacy of compressions. When available, quantitative end-tidal CO$_2$ monitoring is a reasonable adjunct to monitor the adequacy of CPR (goal: >10 mm Hg). If an abrupt rise in end-tidal CO$_2$ is seen in the absence of a dose of bicarbonate, this may indicate ROSC.

ACLS: Defibrillation and Rhythm-Based Therapies

Electrocardiographic (ECG) monitoring is necessary during resuscitation to guide appropriate electric and pharmacologic therapy. Until ECG monitoring allows diagnosis of the rhythm, the patient should be assumed to be in VF (see the section “Ventricular Fibrillation and Pulseless Ventricular Tachycardia”).

Most defibrillators currently marketed have built-in monitoring circuitry in the paddles or pads (quick look). On application of the defibrillator paddles, the patient’s ECG is displayed on the monitor screen. This facilitates appropriate initial therapy. For continuous monitoring beyond the first few minutes, a standard ECG monitoring unit should be used.

ECG monitoring must never be relied on without frequent reference to
the patient’s pulse and clinical condition. What appears on the monitor screen to be VF or asystole must not be treated as such unless the patient is found to be without a pulse. An apparently satisfactory rhythm on the monitor must be accompanied by an adequate pulse and blood pressure.

**Defibrillation**

Electric defibrillation is the definitive treatment for most cardiac arrests. It should be delivered as early as possible and repeated frequently until VF or pulseless ventricular tachycardia (VT) has been terminated. Electric defibrillation involves passing an electric current through the heart and causing synchronous depolarization of the myofibrils. As the myofibrils repolarize, the opportunity arises for the emergence of organized pacemaker activity.

Proper use of the defibrillator requires special attention to the following:

1. **Selection of proper energy levels.** This lessens myocardial damage and arrhythmias occasioned by unnecessarily high energies. For biphasic defibrillators, the energy should be 120 to 200 J. For monophasic defibrillators, the energy should be 360 J [57].

2. **Proper asynchronous mode.** The proper mode must be selected if the rhythm is VF. The synchronizing switch must be deactivated or the defibrillator will dutifully await the R wave that will never come. For rapid pulseless VT (approximately 150 to 200 beats per minute), it is best not to attempt synchronization with the R wave because this increases the likelihood of delivering the shock on the T wave. If the countershock should fall on the T wave and induce VF, another unsynchronized countershock must be delivered promptly after confirming pulselessness.

3. **Proper position of the paddles or pads.** This allows the major energy of the electric arc to traverse the myocardium. The anterolateral position requires that one paddle or pad be placed to the right of the upper sternum, just below the clavicle. The other paddle or pad is positioned to the left of the nipple in the left midaxillary line. In the anteroposterior position, one paddle or pad is positioned under the left scapula with the patient lying on it. The anterior paddle or pad is positioned just to the left of the lower sternal border.

4. **Adequate contact between paddles or pads and skin.** This should be ensured, using just enough electrode paste to cover the paddle face without spilling over the surrounding skin. The rescuer should hold the paddles with firm pressure (approximately 25 lb). The pressure should be delivered using the forearms; leaning into the paddles
should be avoided for fear that the rescuer may slip. If defibrillator electrode paddles are used, the skin must be carefully prepared according to the manufacturer’s directions.

5. **No contact with anyone other than the patient.** The rescuer must be sturdily balanced on both feet and not standing on a wet floor. CPR must be discontinued with no one remaining in contact with the patient. It is the responsibility of the person defibrillating to check the patient’s surroundings, ensure the safety of all participants, loudly announce the intention to countershock, and provide the shock. The use of an automatic or semiautomatic defibrillator does not decrease the operator’s need for diligence.

5. If no skeletal muscle twitch or spasm has occurred, the equipment, contacts, and synchronizer switch used for elective cardioversions should be rechecked.

Electric energy delivered in a biphasic waveform is clearly superior to monophasic waveforms for implantable defibrillators (see Chapters 15, 18), but there is a paucity of evidence to show that one waveform is superior over another with regard to ROSC or survival to hospital discharge. External defibrillators are now available with biphasic waveforms.

Excepting symptomatic bradycardia, pacing is no longer recommended during ACLS.

**Ventricular Fibrillation and Pulseless Ventricular Tachycardia**

The primary therapy for VF and VT without a pulse is defibrillation. If the initial shock, *followed by 2 minutes of CPR*, is unsuccessful, then epinephrine, vasopressin, and later amiodarone should be used. Although not included in the most recent 2010 ACLS guidelines, the use of both vasopressin 20 units and epinephrine 1 mg in place of epinephrine alone (for each dose where the below figures call for epinephrine) for the first five doses of epinephrine, along with a single dose of methylprednisolone 40 mg during the first cycle of CPR, improved outcomes in a single large multicenter trial [58]. Until further study, the combination of vasopressin and epinephrine with methylprednisolone should be considered as a reasonable substitute for epinephrine alone in all instances during ACLS. If steroids are given, hydrocortisone 300 mg per day should be given for
up to 7 days and tapered in patients who achieve ROSC. Those who have experienced an acute myocardial infarction should only receive hydrocortisone for 3 days.

Particularly if the arrest has been unwitnessed and defibrillation is not immediately occurring, CPR should be started while placing defibrillator pads and powering on the machine. If amiodarone is unavailable, lidocaine may be given, though the benefit of lidocaine is unproven. Magnesium is only given for torsades de pointes.

**PEA and Asystole**

The algorithm for PEA and asystole is simple: epinephrine should be given every 3 to 5 minutes until a shockable rhythm or ROSC occurs, or until efforts are terminated. Treatment of the underlying causes, the “Hs and Ts” (discussed below) should be addressed. Atropine is no longer recommended as an agent for asystole or PEA.

**Correction of Hypoxia**

Hypoxia should be corrected early during CPR with administration of the highest possible oxygen concentration. Inadequate perfusion, decreased pulmonary blood flow, pulmonary edema, atelectasis, and ventilation–perfusion mismatch all contribute to the difficulty in maintaining adequate tissue oxygenation. Inadequate tissue oxygenation results in anaerobic metabolism, the generation of lactic acid, and the development of metabolic acidosis.

**Correction of Acidosis**

Correction of acidosis (increased H⁺ concentration) must be considered when the arrest has lasted for more than several minutes. *Metabolic acidosis* develops because of tissue hypoxia and conversion to anaerobic metabolism. *Respiratory acidosis* occurs because of apnea or hypoventilation with intrapulmonary ventilation–perfusion abnormalities, and the marked decrease in pulmonary blood flow that exists even with well-performed CPR.

Sodium bicarbonate reacts with hydrogen ions to buffer metabolic acidosis by forming carbonic acid and then carbon dioxide and water. Each 50 mEq sodium bicarbonate generates 260 to 280 mL carbon dioxide, which can be eliminated only through expired air. Because carbon dioxide of exhaled gas during CPR is decreased, the carbonic acid generated by sodium bicarbonate cannot be effectively eliminated. Paradoxic intracellular acidosis is likely to result, and arterial blood gases may not correctly reflect the state of tissue acidosis. The sodium and
osmolar load of bicarbonate is high; excessive administration results in hyperosmolarity, hypernatremia, and worsened cellular acidosis. Sodium bicarbonate is of questionable value in treating the metabolic acidosis during cardiac arrest; it has not been shown to facilitate ventricular defibrillation or survival in cardiac arrest [59–61]. In any case, bicarbonate should not be used during cardiac arrest until at least 10 minutes have passed, the patient is intubated, and the patient has not responded to initial defibrillation and drug intervention. An exception is the patient with known preexisting hyperkalemia in whom administration of bicarbonate is recommended. The use of bicarbonate may also be of value in patients who have a known preexisting bicarbonate-responsive acidosis or a tricyclic antidepressant overdosage, or to alkalinize the urine in drug overdosage. When bicarbonate is used, 1 mEq per kg may be given as the initial dose. When possible, further therapy should be guided by the calculated base deficit. To avoid iatrogenically induced alkalosis, complete correction of the calculated base deficit should be avoided.

Volume Replacement

Increased central volume is often required during CPR, especially if the initial attempts at defibrillation have failed. PEA is particularly likely to be caused either by acute severe hypovolemia (e.g., exsanguination) or by a cardiovascular process for which volume expansion may be a lifesaving temporizing measure (e.g., pericardial tamponade, pulmonary embolism, and septic shock). The usual clues for hypovolemia, such as collapsed jugular and peripheral veins and evidence of peripheral vasoconstriction, are unavailable during cardiac arrest; furthermore, dry mucus membranes and absence of normal secretions (tears and saliva) are unreliable in acute hypovolemia. Most physical findings of tamponade, pulmonary embolism, or septic shock are absent during arrest. Therefore, one must be guided by an appropriate clinical history and have a low threshold to administer volume during CPR.

Simple crystalloids, such as 5% dextrose in water (D₅W), are inappropriate for rapid expansion of the circulatory blood volume. Isotonic crystalloids (0.9% saline and Ringer’s lactate), colloids, or blood is necessary for satisfactory volume expansion. Crystalloids are more readily available, easier to administer, and less expensive than colloids. They are also free of the potential to cause allergic reactions or infections. If the patient has a weak pulse, simple elevation of the legs, or a passive leg raise, may help by promoting venous return to the central circulation. Volume challenges should be given as needed until pulse and blood pressure have been restored or until there is evidence of volume overload.
Venous Access

Although venous access with a reliable intravenous (IV) route must be established early in the course of the resuscitative effort to allow for the administration of necessary drugs and fluids, initial defibrillation attempts and effective CPR should not be delayed for the placement of an IV line. If skills allow, central venous access may be the most reliable, but intraosseous and peripheral IV access are also reasonable options. If medications are delivered via peripheral route, a 20-mL bolus should be used to flush the drug.

Although central lines may be associated with an increased incidence of complications for patients receiving fibrinolytic therapy, they are not an absolute contraindication to its use.

Drugs such as epinephrine, atropine, and lidocaine can be administered via the endotracheal tube if there is delay in achieving venous access. However, this route requires a higher dose to achieve an equivalent blood level, and a sustained duration of action (a “depot effect”) can be expected if there is a return in spontaneous circulation [61]. It is suggested that 3 to 10 times the IV dose of epinephrine be administered when using the endotracheal route. Delivery of the drug to the circulation is facilitated by diluting the drug in 10 mL of sterile water and delivering it through a catheter positioned beyond the tip of the endotracheal tube. Stop chest compressions, spray the solution quickly down the endotracheal tube, and give several quick insufflations before reinitiating chest compressions. Intracardiac injection of epinephrine is to be avoided.
DRUG THERAPY

Sympathomimetic Drugs and Vasopressors

Sympathomimetic drugs act either directly on adrenergic receptors or indirectly by releasing catecholamines from nerve endings. Most useful during cardiac emergencies are the adrenergic agents, which include the endogenous biogenic amines epinephrine, norepinephrine, and dopamine, and the synthetic agent isoproterenol and its derivative dobutamine. Of note, none of the sympathomimetics can be administered in the same line as an alkaline infusion. Extravasation of any agent with α-adrenergic activity can result in tissue necrosis, so they should be infused via a central venous catheter when possible. If extravasation does occur, 5 to 10 mg phentolamine in 10 to 15 mL saline should be infiltrated as soon as possible into the area of extravasation.

Epinephrine

Epinephrine is a naturally occurring catecholamine that has both α- and β-activities. Although epinephrine is the pressor agent used most frequently during CPR, the evidence that it improves the outcome in humans is scant.

Indications for the use of epinephrine include all forms of cardiac arrest because its α-vasoconstrictive activity is important in raising the perfusion pressure of the myocardium and brain. The importance of α-adrenergic activity during resuscitation has been noted in several studies [62], whereas administration of pure β-agonists (e.g., isoproterenol or dobutamine) has been shown to be ineffective [63]. The β-action of epinephrine is theoretically useful in asystole and bradycardic arrests by increasing heart rate. The β-effect has also been touted to convert asystole to VF or to convert “fine” VF to “coarse.” Coarse or wide-amplitude VF is easier to convert to a perfusing rhythm than fine or small-amplitude VF. However, this may be primarily due to the shorter time course of the arrest in patients still manifesting wide-amplitude rather than small-amplitude VF.

Epinephrine is best administered intravenously. As soon as possible after failed ventricular defibrillation attempts (or if defibrillation is not an option), an adult in cardiac arrest should be given a 1-mg dose at a 1 to 10,000 dilution (10 mL). It should be given in the upper extremity or centrally (see the earlier discussion in the section “Venous Access”), and may be repeated every 5 minutes. If a peripheral line is used, the drug should be administered rapidly and followed by a 20-mL bolus of IV fluid.
and elevation of the extremity. If an IV line has not been established, the endotracheal route may be used, but the intracardiac route should be avoided because it is prone to serious complications such as intramyocardial injection, coronary laceration, and pneumothorax. An IV infusion of 1 to 10 mcg per minute can also be given for inotropic and pressor support. Two multicenter trials evaluating the effectiveness of high-dose epinephrine in cardiac arrest failed to demonstrate an improvement in survival or neurologic outcome [64,65], and doses above 1 mg (excepting endotracheal administration) should not be used.

Risks in the use of epinephrine and other α-agonists include tissue necrosis from extravasation and inactivation from admixture with bicarbonate.

Norepinephrine

Norepinephrine is a potent α-agonist with β-activity. Its salutary α-effects during CPR are similar to those of epinephrine [66]. However, there are no data to support that it is superior to epinephrine during an arrest.

The major effect of norepinephrine is on the blood vessels. Initial coronary vasoconstriction usually gives way to coronary vasodilatation, probably as a result of increased myocardial metabolic activity. In a heart with compromised coronary reserve, this may cause further ischemia. During cardiac arrest, its usefulness, like that of epinephrine, is most likely due to peripheral vasoconstriction with an increase in perfusion pressure. In patients with spontaneous circulation who are in cardiogenic shock (when peripheral vasoconstriction is often already extreme), its effect is more difficult to predict.

Indications for the use of norepinephrine during cardiac arrest are similar to those for epinephrine, although there does not appear to be any reason to prefer it to epinephrine. Norepinephrine appears to be most useful in the treatment of shock caused by inappropriate decline in peripheral vascular resistance, such as septic shock and neurogenic shock. It is administered by IV infusion and titrated to an adequate perfusion pressure. Norepinephrine bitartrate, 4 to 8 mg (2 to 4 mg of the base), should be diluted in 500 mL D₅W or 5% dextrose in normal saline. A typical starting infusion rate is 0.5 mcg per minute and most adults respond to 2 to 12 mcg per minute, but some require rates up to 30 mcg per minute. Abrupt termination of the infusion (as may occur in transport) may lead to sudden severe hypotension.

Precautions to the use of norepinephrine include its inappropriate use in hypovolemic shock and in patients with already severe vasoconstriction. Intraarterial pressure monitoring is recommended when using norepinephrine because indirect blood pressure measurement is often incorrect in patients with severe vasoconstriction.
In patients with myocardial ischemia or infarction, the myocardial oxygen requirements are increased by all catecholamines, but there is limited evidence to guide vasopressor selection in this population. Heart rate, rhythm, ECG evidence for ischemia, direct systemic and pulmonary pressures, urine output, and cardiac output should be closely monitored when using this drug in patients with myocardial ischemia or infarction.

**Isoproterenol**

This synthetic catecholamine has almost pure $\beta$-adrenergic activity. Its cardiac activity includes potent inotropic and chronotropic effects, both of which will increase the myocardium’s oxygen demand. In addition to bronchodilatation, the arterial beds of the skeletal muscles, kidneys, and gut dilate, resulting in a marked drop in systemic vascular resistance. Cardiac output can be expected to increase markedly unless the increased myocardial oxygen demand results in substantial myocardial ischemia. Systolic blood pressure is usually maintained because of the rise in cardiac output, but the diastolic and mean pressures usually decrease. As a result, coronary perfusion pressure drops at the same time that the myocardial oxygen requirement is increased. This combination can be expected to have deleterious effects in patients with ischemic heart disease, especially during cardiac arrest. The main clinical usefulness of isoproterenol is in its ability to stimulate pacemakers within the heart.

Indications for isoproterenol are primarily in the setting of atropine-resistant, hemodynamically significant bradycardias, including profound sinus and junctional bradycardia, as well as various forms of high-degree AV block. It should be used only as an interim measure, until effective transcutaneous or IV pacing can be instituted. If the aortic diastolic pressure is already low, epinephrine is likely to be better tolerated as a stimulus to pacemakers. *Under no circumstances should isoproterenol be used during cardiac arrest.*

Isoproterenol is administered by titration of an IV solution. 1 mg isoproterenol (Isuprel) is diluted with either 250 mL D$_5$W (4 mg per mL) or 500 mL D$_5$W (2 mg per mL). The infusion rate should be only rapid enough to effect an adequate perfusing heart rate (2 to 20 mcg per minute, or 0.05 to 0.5 mcg per kg per minute). Depending on the adequacy of cardiac reserve, a target heart rate as low as 50 to 55 beats per minute may be satisfactory. Occasionally, more rapid rates are necessary.
Precautions in the use of isoproterenol are largely due to the increase in myocardial oxygen requirement, with its potential for provoking ischemia; this effect, coupled with the possibility of dropping the coronary perfusion pressure, makes isoproterenol a dangerous selection in patients with myocardial ischemia. The marked chronotropic effects may cause tachycardia and provoke serious ventricular arrhythmias, including VF. Isoproterenol is usually contraindicated if tachycardia is already present, especially if the arrhythmia may be secondary to digitalis toxicity. If significant hypotension develops with its use, it may be combined with another β-agonist with α-activity. However, switching to dopamine or epinephrine is usually preferable; better yet is the use of pacing for rate control.

Dopamine

This naturally occurring precursor of norepinephrine has α-, β-, and dopamine-receptor–stimulating activities. The dopamine-receptor activity theoretically dilates renal and mesenteric arterial beds at low doses (1 to 2 mcg per kg per minute), though the clinical relevance of this is unclear [67]. β-Adrenergic activity is more prominent with doses from 2 to 10 mcg per kg per minute, whereas α-adrenergic activity is predominant at doses greater than 10 mcg per kg per minute. It has not been shown that these dose ranges have relevance in the clinical setting. Indications for the use of dopamine are primarily significant hypotension and cardiogenic shock.

Dopamine is administered by IV titration in the range of 2 to 20 μg per kg per minute. Rarely, a patient may need in excess of 20 mcg per kg per minute. A 200-mg ampule is diluted to 250 or 500 mL in D₅W or 5% dextrose in normal saline for a concentration of 800 or 400 mg per mL. As with all catecholamine infusions, the lowest infusion rate that results in satisfactory perfusion should be the goal of therapy.

Precautions for dopamine are similar to those for other catecholamines. Tachycardia or ventricular arrhythmias may require reduction in dosage or discontinuation of the drug. If significant hypotension occurs from the dilating activity of dopaminergic or β-active doses, small amounts of an α-active drug may be added. Dopamine may increase myocardial ischemia.

Dobutamine

Dobutamine is a potent synthetic β-adrenergic agent that differs from isoproterenol in that tachycardia is less problematic. Unless ischemia supervenes, cardiac output will increase, as will renal and mesenteric blood flow.
Dobutamine is indicated primarily for the short-term enhancement of ventricular contractility in the patient with heart failure. It may be used for stabilization of the patient after resuscitation or for the patient with heart failure refractory to other drugs. It may also be used in combination with IV nitroprusside, which lowers peripheral vascular resistance and thereby left ventricular afterload. Although nitroprusside lowers peripheral resistance, dobutamine maintains perfusion by augmenting the cardiac output.

Dobutamine is administered by slow-titrated IV infusion. A dose as low as 0.5 mcg per kg per minute may prove to be effective, but the usual dose range is 2.5 to 10.0 mcg per kg per minute. A 250-mg vial is dissolved in 10 mL of sterile water and then to 250 or 500 mL D$_5$W for a concentration of 1.0 or 0.5 mcg per mL.

Precautions for dobutamine are similar to those for other β-agonists. Dobutamine may cause tachycardia, ventricular arrhythmias, myocardial ischemia, and extension of infarction.

**Vasopressin**

Vasopressin is not a catecholamine, but a naturally occurring antidiuretic hormone. In high doses, it is a powerful constrictor of smooth muscles and as such has been studied as an adjunctive therapy for cardiac arrest in an attempt to improve perfusion pressures and organ flows. Vasopressin may be especially useful in prolonged cardiac arrest as it remains effective as a vasopressor even in severe acidosis [68]. It may be used as a first-line agent in arrest in lieu of epinephrine or as the second-line agent if the first dose of epinephrine failed to cause a return in pulse. The dose of vasopressin is 40 units IV or intraosseously (IO). It may also be used in combination with epinephrine 1 mg and methylprednisolone 40 mg (once) at 20 units for each cycle of ACLS [58].

**Antiarrhythmic Agents**

Antiarrhythmic agents have been thought to play an important role in stabilizing the rhythm in many resuscitation situations; however, the data in support of their value are scant. Although lidocaine, bretylium, and procainamide had been considered useful in counteracting the tendency to ventricular arrhythmias, convincing evidence of benefit to their use for pulseless VT and VF is wanting. On the basis of available data, amiodarone is the agent of choice for the emergency treatment of refractory VT and VF [69].

**Amiodarone**
Amiodarone is a benzofuran derivative that is structurally similar to thyroxine and contains a considerable level of iodine. Gastrointestinal absorption is slow; therefore, when given orally, the onset of action is delayed while the drug slowly accumulates in adipose tissue. The mean elimination half-life is 64 days (range, 24 to 160 days). IV administration allows rapid onset of action, with therapeutic blood levels achieved with 600 mg given over 24 hours.

Amiodarone decreases myocardial contractility and also causes vasodilatation, which counterbalances the decrease in contractility. In general, it is well tolerated even by those with myocardial dysfunction.

Amiodarone given IV has been successful in terminating a variety of reentrant and other types of supraventricular and ventricular rhythms. In a major study of out-of-hospital cardiac arrest due to ventricular arrhythmias refractory to shock, patients were initially treated with either amiodarone (246 patients) or placebo (258 patients). Patients given amiodarone had a higher incidence of bradycardia (41% vs. 25%) and hypotension (59% vs. 48%), besides a higher rate of survival to hospital admission (44% vs. 34%) [69]. This study did not demonstrate an increase in survival to hospital discharge or in neurologic status. On the basis of this study, amiodarone has been given status as an option for use after defibrillation attempts and epinephrine therapy in refractory ventricular arrhythmias during cardiac arrest. It is also an option for ventricular rate control in rapid atrial arrhythmias in patients with impaired left ventricular function. Other optional uses are for control of hemodynamically stable VT, polymorphic VT, preexcited atrial arrhythmias, and wide-complex tachycardia of uncertain origin. It may also be useful for chemical cardioversion of atrial fibrillation or as an adjunct to electric cardioversion of refractory paroxysmal supraventricular tachycardia (PSVT) and atrial fibrillation or flutter.

Administration in cardiac arrest (pulseless VT or VF) is by rapid IV infusion of 300 mg diluted in 20 to 30 mL of saline or D₅W.

Supplementary infusions of 150 mg may be used for recurrent or refractory VT or VF.

Administration for rhythms with a pulse is by IV infusion of 150 mg given for 10 minutes, followed by infusion of 1 mg per minute for 6 hours and then 0.5 mg per minute. Supplemental infusions of 150 mg may be given for recurrent or resistant arrhythmias to a total maximum dose of 2 g for 24 hours.
**Lidocaine**

This antiarrhythmic agent has been used for ventricular arrhythmias, such as premature ventricular complexes and VT. Premature ventricular complexes are not unusual in apparently healthy people and most often are benign. Even in the patient with chronic heart disease, premature ventricular complexes and nonsustained VT are usually asymptomatic, and controversy exists concerning the need to treat under these circumstances.

Administration of lidocaine begins with an IV bolus. The onset of action is rapid. Its duration of action is brief, but may be prolonged by continuous infusion. A solution of lidocaine, typically 20 mg per mL (2%), should be prepared for IV administration. If the patient has suffered an acute myocardial infarction and has had ventricular arrhythmias, the infusion is continued for hours to days and tapered slowly. If the cause of the arrhythmia has been corrected, the infusion may be tapered more rapidly.

Precautions should be taken against excessive accumulation of lidocaine. The dosage should be reduced in patients with low cardiac output, congestive failure, hepatic failure, and age older than 70 years because of the decreased liver metabolism of the drug. Toxic manifestations are usually neurologic, and can vary from slurred speech, tinnitus, sleepiness, and dysphoria to localizing neurologic symptoms. Frank seizures may occur with or without preceding neurologic symptoms and may be controlled with short-acting barbiturates or benzodiazepines. Conscious patients should be warned about possible symptoms of neurologic toxicity and asked to report them immediately if they occur. Excessive blood levels can significantly depress myocardial contractility.

**Adenosine**

Adenosine is an endogenous purine nucleoside that depresses AV nodal conduction and sinoatrial nodal activity. Because of the delay in AV nodal conduction, adenosine is effective for terminating arrhythmias that use the AV node in a reentrant circuit (e.g., PSVT) [70]. For supraventricular tachycardias, such as atrial flutter or atrial fibrillation, or atrial tachycardias that do not use the AV node in a reentrant circuit, blocking transmission through the AV node may prove helpful in clarifying the diagnosis [71,72]. In the 2010 ACLS guidelines, the use of adenosine in wide-complex tachycardia of uncertain origin to discriminate between VT and supraventricular tachycardia with aberrancy is encouraged. Adenosine may also be used in the diagnosis and treatment of stable and unstable narrow complex tachycardias. The half-life of adenosine is less
than 5 seconds because it is rapidly metabolized. Administration is by IV bolus of 6 mg given for 1 to 3 seconds, followed by a 20-mL saline flush. An additional dose of 12 mg may be given if no effect is seen within 1 to 2 minutes. Patients taking theophylline may need higher doses.

Side effects caused by adenosine are transient and may include flushing, dyspnea, bronchoconstriction, and angina-like chest pain (even in the absence of coronary disease). Sinus bradycardia and ventricular ectopy are common after terminating PSVT with adenosine, but the arrhythmias are typically short lived so as to be clinically unimportant. The reentrant tachycardia may recur after the effect of adenosine has dissipated and may require additional doses of adenosine or a longer acting drug, such as verapamil or diltiazem.

Theophylline and other methylxanthines, such as theobromine and caffeine, block the receptor responsible for adenosine’s electrophysiologic effect; therefore, higher doses may be required in their presence. Dipyridamole and carbamazepine, on the other hand, potentiate and may prolong the effect of adenosine; therefore, other forms of therapy may be advisable. Be careful not to give to asthmatics.

**Verapamil and Diltiazem**

Unlike other calcium channel–blocking agents, verapamil and diltiazem increase refractoriness in the AV node and significantly slow conduction. This action may terminate reentrant tachycardias that use the AV node in the reentrant circuit (e.g., PSVT). These drugs may also slow the ventricular response of patients with atrial flutter or fibrillation and even for patients with multifocal atrial tachycardia. They should be used only for patients for whom the tachycardia is known to be supraventricular in origin.

Administration of verapamil is by IV bolus of 2.5 to 5.0 mg for 2 minutes. In the absence of a response, additional doses of 5 to 10 mg may be given at 15- to 30-minute intervals to a maximum of 20 mg. The maximum cumulative dose is 20 mg. Diltiazem may be given as an initial dose of 0.25 mg per kg with a follow-up dose of 0.35 mg per kg, if needed. A maintenance infusion of 5 to 15 mg per hour may be used to control the rate of ventricular response in atrial fibrillation.

Verapamil and diltiazem should be used for arrhythmias known to be supraventricular in origin and in the absence of preexcitation. Both verapamil and diltiazem may decrease myocardial contractility and worsen congestive heart failure or even provoke cardiogenic shock in patients with significant left ventricular dysfunction. They should, therefore, be used with caution in patients with known cardiac failure or suspected diminished cardiac reserve and in the elderly. If worsened
failure or hypotension develops after the use of these agents, calcium should be administered, as described in the section “Other Agents.”

**Magnesium**

Cardiac arrhythmias and even sudden cardiac death have been associated with magnesium deficiency [72]. Hypomagnesemia decreases the uptake of intracellular potassium and may precipitate VT or fibrillation. Routine use of magnesium in cardiac arrest or after myocardial infarction is not recommended. Magnesium may be of value for patients with torsades de pointes, even in the absence of hypomagnesemia.

Magnesium is administered IV. For rapid administration during VT or VF with suspected or documented hypomagnesemia, 1 to 2 g may be diluted in 100 mL of D₅W and given for 1 to 2 minutes. A 24-hour infusion of magnesium may be used for periinfarction patients with documented hypomagnesemia. A loading dose of 1 to 2 g is diluted in 100 mL D₅W and slowly given for 5 minutes to 1 hour, followed by an infusion of 0.5 to 1 g per hour during the ensuing 24 hours. Clinical circumstances and the serum magnesium level dictate the rate and duration of the infusion. Hypotension or asystole may occur with rapid administration.

**Other Agents**

Additional drugs occasionally found useful or necessary during resuscitation or in the immediate postresuscitation period include atropine, calcium, nitroprusside, and nitroglycerine; these agents are discussed in the following sections. Many other drugs may be required in particular circumstances and are discussed in other parts of this text. An incomplete list of these drugs includes beta-blockers, ibutilide, propafenone, flecainide, sotalol, digoxin, antibiotics, thiamine, thyroxine, morphine, naloxone, adrenocorticoids, fibrinolytic agents, anticoagulants, antiplatelet agents, and dextrose.

**Atropine Sulfate**

Atropine is an anticholinergic drug that increases heart rate by stimulating pacers and facilitating AV conduction that is suppressed by excessive vagal tone. Atropine is indicated primarily for bradycardias causing hemodynamic difficulty or associated with ventricular arrhythmias. Atropine may be
useful in AV block at the nodal level. It is no longer used in asystole and bradycardic arrests.

Atropine is administered by IV bolus. If a satisfactory response has not occurred within 3 to 5 minutes, additional 1-mg doses should be given in a bolus, to a maximum dose of 3 mg (0.04 mg per kg). For bradycardia with a pulse, the initial dose should be 0.5 mg repeated every 5 minutes until the desired effect is obtained, to a maximum dose of 3 mg (0.04 mg per kg). Atropine may be given by the endotracheal route at doses 2.5 times the IV dose.

Precautions for atropine include the requirement that an inordinately rapid heart rate not be produced. Patients with ischemic heart disease are likely to have worsened ischemia or ventricular arrhythmias if the rate is too rapid. Uncommonly, a patient will have a paradoxical slowing of rate with atropine; this is more likely to occur with smaller first doses and is caused by a central vagal effect. This effect is rapidly counteracted by additional atropine. In this situation, the next dose of atropine should be given immediately. If additional atropine does not correct the problem, the patient may require judicious use of isoproterenol or pacemaker therapy.

Calcium

The positive inotropic effect of calcium has led to its use in cardiac arrest. The contractile state of the myocardium depends in part on the intracellular concentration of the calcium ion. Transmembrane calcium flux serves an important regulatory function in both active contraction and active relaxation. The use of calcium in cardiac arrest is based on an early report by Kay and Blalock [73] in which several pediatric cardiac surgical patients were successfully resuscitated, apparently with the aid of calcium. However, several field studies have failed to demonstrate an improvement in survival or neurologic outcome with the use of calcium versus a control [74]. In addition, after standard doses of calcium administered during cardiac arrest, many patients are found to have very high calcium blood levels [75]. This is apparently due to the markedly contracted volume of distribution of the ion in the arrested organism. In addition, calcium has the theoretic disadvantage of facilitating postanoxic tissue damage, especially in the brain and heart. Digitalis toxicity may be exacerbated by the administration of calcium.

Calcium is indicated only in specific circumstances: calcium channel blocker toxicity, severe hyperkalemia, severe hypocalcemia, arrest after multiple transfusions with citrated blood, fluoride toxicity, and while coming off heart–lung bypass after cardioplegic arrest.

Calcium is available as calcium chloride, calcium gluceptate, and calcium gluconate. The gluconate salt is unstable and less frequently
available. The chloride salt provides the most direct source of calcium ion and produces the most rapid effect. The gluceptate and gluconate salts require hepatic degradation to release the free calcium ion. Calcium chloride is, therefore, the best choice. It is highly irritating to tissues and must be injected into a large vein with precautions to avoid extravasation. Calcium chloride is available in a 10% solution. An initial dose of 250 to 500 mg may be administered slowly during several minutes. It may be repeated as necessary at 10-minute intervals if strong indications exist.

Precautions for calcium use include the need for slow injection without extravasation. If bicarbonate has been administered through the same line, it must be cleared before introducing the calcium. If the patient has a rhythm, rapid injection may result in bradycardia. Calcium salts must be used with caution in patients receiving digitalis.
CLINICAL SETTINGS

The procedures involved in the resuscitation of a person who has experienced cardiovascular or respiratory collapse are all part of a continuum progressing from the initial recognition of the problem and the institution of CPR to intervention with defibrillators, drugs, pacemakers, transport, and postresuscitative evaluation and care. The following sections focus on the pharmacologic and electric interventions appropriate to various clinical settings common in cardiac arrest.

Special Situations

Patients who have nearly drowned in cold water may recover after prolonged periods of submersion. Apparently, the hypothermia and bradycardia of the diving reflex may serve to protect against organ damage [76]. Successful resuscitation has been described after considerable periods of submersion [76]. Because it is often difficult for bystanders and rescuers to estimate the duration of submersion, in most cases it is warranted to initiate CPR at the scene, unless physical evidence exists of irreversible death, such as putrefaction or dependent rubor.

Hypothermia may occur with environmental exposures other than cold water drowning. The body’s ability to maintain temperature is diminished by alcohol, sedation, antidepressants, neurologic problems, and advanced age. Because of the associated bradycardia and oxygen-sparing effects, prolonged hypothermia and arrest may be tolerated with complete recovery. A longer period may be needed to establish breathlessness and pulselessness because of profound bradycardia and slowed respiratory rate. Resuscitative efforts should not be abandoned until near-normal temperature has been reestablished.

Electric shock and lightning strike may lead to tetanic spasm of respiratory muscles or convolution, causing respiratory arrest. VF or asystole may occur from the electric shock or after prolonged respiratory arrest. Before initiating assessment and CPR, the potential rescuer must ascertain whether the person who has been shocked is still in contact with the electric energy and that live wires are not in dangerous proximity. If the individual is located at the top of a utility pole, CPR is best instituted after the person is lowered to the ground [77].

Termination of ACLS and Post ACLS Care

Induced therapeutic hypothermia (32°C to 34°C) for 12 to 24 hours improves survival and neurologic outcome in comatose patients who have
survived an out-of-hospital VF arrest [78,79]. More recent evidence suggests that targeting a temperature of 36°C rather than 33°C may offer the same benefit, and has the advantage of less infectious risks and easier use of existing literature to help determine prognosis [16]. Hypothermia may also be beneficial for in-hospital arrests, though evidence is lacking. Lower cardiac index and hyperglycemia tend to occur more frequently in hypothermic patients, as do infections [80]. Shivering must be prevented to reduce the risk of increasing the metabolic rate. Please see Chapter 184 on hypothermia for an in-depth discussion of induced therapeutic hypothermia.

When to stop CPR or CLS is not always clearly defined. For emergency room patients with a rhythm of either PEA or asystole, there were no cases of ROSC when cardiac standstill was demonstrated by echocardiography [81]. Providers considering use of echo to assist in deciding to terminate resuscitative efforts should consider their own skill in performing echocardiography and the overall clinical situation. The ethics section of the ACLS guidelines suggests criteria for limiting resuscitation in several settings [48]. CPR should not begin in any setting when a valid do-not-resuscitate (DNR) order exists, when it is unsafe for the provider or rescuer, or when obvious signs of death are present such as rigor mortis, dependent livedo, decapitation, or decomposition. If CPR is begun, it is stopped when ROSC is achieved, the provider is too exhausted to continue, or when care is handed off to another provider team. Out-of-hospital arrest resuscitation (BLS and ALCS) may also be terminated if patients meet all three of the following criteria: (1) arrest not witnessed by EMS personnel; (2) no defibrillation attempted before transport; and (3) no ROSC before transport [48,82]. For most patients who undergo resuscitation but do not achieve ROSC, the decision to terminate resuscitation efforts is often based on the clinical situation, including factors such as whether a pulse was obtained at some point during the resuscitation, premorbid state, initial rhythm, arrest duration both before starting CPR and duration of the resuscitation. Prearrest functional status and duration of resuscitation impact survival [83,84]. Duration of CPR is often the simplest decision criterion, and while there is no well-defined threshold, after 10 to 30 minutes of CPR, survival is unlikely [84–86].

Arrests in the ICU are often felt to have a very poor prognosis. However, among ICU arrest patients for whom resuscitation is attempted, one 5-year series reported surprisingly good outcomes, with 1 and 5 year survivals of 24% and 16%, respectively [86]. Many ICU arrests
can be anticipated and communication with patients and families with an emphasis on advanced care decision-making are often the most important aspects of resuscitation management in the ICU.

Utility of Ultrasonography for Cardiopulmonary Resuscitation

Ultrasonography has utility during the performance of CPR. Focused echocardiography can be performed during the pauses in CPR intended for checks of ROSC [87], and does not impair the quality of CPR when the no-flow period is not extended [88,89].

The operator is positioned such that a subcostal long axis view can be obtained during pulse checks. This requires that a portable ultrasonography machine be placed at the thigh level of the patient as close to the bed as possible with the screen adjusted for optimal image clarity. The operator faces the screen while pressing the probe into the subcostal area in anticipation of the pulse check. Machine setup and operator positioning are not permitted to interrupt chest compressions, as these take absolute priority. When the code team leader alerts the team that a pulse check is required, a team member assumes position contralateral to the ultrasonography machine to prepare to manually check for a pulse in the femoral area, while the ultrasonography operator pre-positions the probe in order to obtain an immediate subcostal long axis view of the heart during the pulse check. When the code leader orders that chest compressions stop for the 5-second pulse check, a skilled scanner can obtain a good quality view of the heart. During chest compressions, it is not possible to obtain any useful images due to the marked translational movement of the heart that occurs during chest compressions (Videos 14.1 and 14.2).

If the CPR team is so equipped, a transesophageal echocardiography probe can be easily inserted during CPR. This can only be performed if the patient has a well secured endotracheal tube in place. The probe is inserted with 0° transducer rotation to obtain the transgastric short axis view of the left ventricle. In this way, the CPR effort is monitored both during chest compressions and pulse checks (Videos 14.3 and 14.4).

Limited view transthoracic echocardiography is useful during CPR for three reasons:

1. Identification of potentially reversible causes of cardiac arrest such as a large pericardial effusion with tamponade, a severely dilated right ventricle with acute cor pulmonale related to a pulmonary embolism, or a heart that is profoundly hypovolemic. These findings are uncommon during CPR; however, when found, they may result in a
lifesaving intervention (Videos 14.5, Video 14.6, and Video 14.7).

2. Identification of cardiac contractile activity without palpable pulse (pseudo PEA). Echocardiographic imaging during CPR allows reclassification of some patients who are clinically classified as having pulseless electrical activity, because even very weak endogenous cardiac contractility can be observed sonographically (Videos 14.8 and 14.9). The prognosis for ROSC is improved when there is some echocardiographic evidence of endogenous myocardial contractility [90]. This finding is not uncommon, and leads to the consideration that resuscitation efforts should be continued if the clinical situation warrants this.

3. Identification of the absence of cardiac contractile activity. In the patient who is receiving CPR in the emergency department, complete absence of cardiac contractile activity is a strong indicator that the resuscitation effort will not be successful [91] (Videos 14.10 and 14.11). In ICU patients, the absence of endogenous myocardial contractility on echocardiography performed during CPR confers a significantly lower likelihood of ROSC and very low likelihood of survival to hospital discharge compared to finding the presence of cardiac contractile activity [92,93]. While the absence of cardiac contractile activity is not an absolute indicator that the CPR effort will fail, it may combine with other clinical indicators in the decision to terminate CPR attempts.

Ultrasonography is also useful for detecting correct endotracheal tube placement during CPR. Unintentional esophageal intubation may be difficult to detect during CPR because end-tidal CO$_2$ levels may not be detectable in full cardiac arrest, and chest auscultation may not be accurate. Laryngeal ultrasonography examination during endotracheal intubation allows detection of correct insertion of the endotracheal tube into the trachea in patients receiving CPR [94], and the presence of bilateral lung sliding with bag ventilation confirms correct tube position in the trachea [95] (Videos 14.12 and 14.13).

Interosseous needle insertion provides rapid access for drug delivery during CPR. Ultrasonography may be used to confirm intraosseous (I/O) needle placement [96,97]. At the tibial insertion site, the operator places the linear vascular probe next to the holding flange of the I/O needle while angling the scanning plane toward the needle tip. The periosteum of the anterior tibia appears as a distinct hyperechoic line. The color Doppler map is positioned below the periosteum and 5 cc of sterile saline is injected into the I/O needle. If the needle is well positioned, a color Doppler signal will result deep to the periosteum during the injection (Video 14.14). A color Doppler signal that is seen superficial to the
periosteum indicates misplacement of the needle with the risk of extravasation of adrenergic medication into the subcutaneous compartment.

The use of electric shock to terminate arrhythmia is one of the sentinel medical advances of the last century and underlies much of the modern treatment of arrhythmias. Thanks to the pioneering work of Zoll and Lown in the late 1950s and early 1960s, the use of electric shock gained widespread acceptance. Although incorporating the same mechanism and physics, cardioversion refers to the use of direct-current electric shock to terminate arrhythmias other than ventricular fibrillation (VF), whereas defibrillation refers to the termination of VF. Cardioversion shocks are delivered at the time of the electrical QRS complex (to avoid the initiation of VF which may result from shocks on the T-wave) while defibrillation occurs with an unsynchronized shock.

PHYSIOLOGY OF ARRHYTHMIA AND SHOCK

Arrhythmias require both a trigger for initiation and an appropriate substrate for maintenance. Arrhythmias may be due to reentry, increased automaticity, or triggered activity. Many of the commonly encountered arrhythmias are due to a fixed reentrant mechanism, including atrial flutter (AFL), atrioventricular nodal reentrant tachycardia (AVNRT), AV reentrant tachycardia (AVRT), and most ventricular tachycardias (VT). Atrial fibrillation (AF), once thought exclusively initiated by reentry, has also been shown to be initiated by automatic foci in the pulmonary veins in many individuals [1,2]. AF appears to be maintained by one of three mechanisms: functional reentry, one or more rapidly firing foci from an
autonomic cardiac ganglion plexi, or “rotors” [2]. VF is also due to functional reentry. Cardioversion and defibrillation terminate these arrhythmias by simultaneously depolarizing all excitable tissue, disrupting the process of reentry.

Arrhythmias may also be due to disorders of impulse formation (increased automaticity or triggered activity). These include sinus tachycardia, focal atrial tachycardia (AT), and idiopathic VT (i.e., VT in a structurally normal heart). Sinus tachycardia is a physiologic response and not a pathologic tachycardia; thus sinus tachycardia will not respond to cardioversion, but AT and VT generally will terminate.

Insight into the effect of shock on fibrillating myocardial cells has grown in the past few decades. Although it was initially thought that all activation fronts had to be terminated simultaneously to stop AF and VF, it is now believed that if the vast majority of myocardium is silenced, the remaining mass is insufficient to perpetuate the arrhythmia. The effect of shock on the fibrillating myocardium is complex and is dependent on multiple factors including energy, waveform, and myocardial refractory state [3]. Electrical shocks at low energy levels may fail to terminate AF and VF. And finally, VF can be triggered in patients not already in this rhythm if shock occurs on a vulnerable portion of the T-wave. Thus, synchronization of shocks with the R-wave will minimize the risk of VF.
INDICATIONS AND CONTRAINDICATIONS

Cardioversion and defibrillation are performed for a variety of reasons in the intensive care setting. In the case of hemodynamic instability due to tachyarrhythmia of nearly any type, the urgent use of shock is strongly indicated. One must be careful, however, not to shock sinus tachycardia, which is commonly present in patients who are hypotensive for noncardiac reasons, as doing so may provoke arrhythmias. Acute congestive heart failure and angina that are secondary to an acute tachyarrhythmia are also indications for urgent cardioversion; however, there is usually sufficient time to provide some anesthesia. In the absence of hemodynamic instability or significant symptoms, cardioversion is usually considered elective and the risks and benefits of the procedure must be carefully weighed.

Extreme caution should be exercised in patients with digitalis toxicity or electrolyte imbalance because of their increased risk of VT or fibrillation after being shocked. Patients with severe sinus node disease may exhibit significant bradyarrhythmia after cardioversion from AF. In addition, patients who have been in AF for greater than 48 hours are at risk of thromboembolism after cardioversion; appropriate measures should be taken to minimize this risk (see below) [2].
A clinical competence statement by the American College of Cardiology and American Heart Association outlines the cognitive and technical skills required for the successful and safe performance of elective external cardioversion (Table 15.1). A minimum of eight cardioversions should be supervised before a physician is considered to be competent to perform the procedure independently. In addition, a minimum of four procedures should be performed annually to maintain competence [4].

### Table 15.1 Cognitive and Technical Skills Necessary for Performing External Cardioversion

Physicians should have knowledge of the following:
- Electrophysiologic principles of cardioversion
- Indications for the procedure
- Anticoagulation management
- Proper use of antiarrhythmic therapy
- Use of sedation and the management of overdose
- Direct current cardioversion equipment, including the selection of appropriate energy and synchronization
- Treatment of possible complications, including ACLS, defibrillation, and pacing
- Proper placement of paddles or pads
- Appropriate monitor display and recognition of arrhythmias
- Ability to differentiate failure to convert atrial fibrillation from an immediate recurrence of atrial fibrillation
- Baseline 12-lead electrocardiogram reading, recognition of acute changes, drug toxicity, and contraindications

Physicians should have the following technical skills:
- Proper preparation of skin and electrode placement, including application of saline jelly or saline-soaked gauze
- Achievement of artifact-free monitored strips and synchronization signal/marker
- Technically acceptable 12-lead electrocardiograms before and after DCCV
Temporary pacing and defibrillation capabilities
Ability to perform advanced cardiac life support, including proper airway management

Methods

Patient Preparation

In the case of unconsciousness due to tachyarrhythmia, shock must be performed emergently. In more elective settings, patient safety and comfort become paramount. As with any procedure, informed consent should be obtained. In elective settings, patients should refrain from eating and drinking for several hours in order to decrease the risk of aspiration (6 hours for solids, 2 hours for clear liquids). Constant heart rhythm monitoring should be used throughout the procedure, and a 12-lead electrocardiogram should be obtained before and after the shock.

Medications with rapid onset and short half-life are favored for achieving analgesia, sedation, and amnesia. The combination of a benzodiazepine, such as midazolam, and a narcotic, such as fentanyl, is a common choice in the absence of anesthesiology assistance. Propofol is often used when an anesthesiologist is present to assist with airway management and sedation. Existing hospital policies for monitoring during conscious sedation should be followed, including frequent assessment of blood pressure and pulse oximetry. Supplemental oxygen is delivered via nasal cannula, face mask, or, in the case of heavier sedation, an Ambu bag. The goal of sedation should be minimal or no response to verbal stimulus.

Shock Waveforms

Defibrillators that employ biphasic waveforms have largely replaced those utilizing monophasic waveforms. Advantages of biphasic waveforms are lower defibrillation thresholds, meaning shocks using biphasic waveforms require less energy to achieve defibrillation, and they are less likely to cause skin burns and myocardial damage [3]. Biphasic truncated exponential waveform and biphasic rectilinear waveform are both commercially available, with the former being more common.
Randomized trials comparing the two types of biphasic waveforms in the cardioversion of AF have failed to show any significant difference in efficacy [5–7].

The efficacy of biphasic shocks in the termination of VF has been well established [8]. Furthermore, clinical studies of AF cardioversion have established the superiority of biphasic over monophasic waveform shocks [9]. For instance, one study demonstrated the equivalent efficacy of a 120 to 200 J biphasic sequence with a 200 to 360 J monophasic sequence [9]. Biphasic waveforms allow fewer shocks to be given and a lower total energy delivery. Whether or not this translates into a significant clinical advantage remains to be demonstrated. However, there is evidence that biphasic shocks result in less dermal injury, and no significant difference in myocardial damage [10]. Although an animal model suggested better maintenance of cardiac function after biphasic shocks, human data on myocardial function are not yet available [11].

**Electrodes**

Self-adhesive pads and handheld paddles are employed for cardioversion and defibrillation. Limited data are available comparing the two modalities, but one study suggested the superiority of paddles over pads in cardioverting AF [12]. This phenomenon might be explained by the lower transthoracic impedance achieved with paddles. Whichever modality is used, impedance can be minimized by avoiding positioning over breast tissue, by clipping body hair when it is excessive, by delivering the shock during expiration, and by firm pressure on the pads or paddles. Burns secondary to self-adhesive pads are common and very rarely observed with paddles.

The optimal anatomic placement of pads and paddles is not clear; however, the general principal holds that the heart must lie between the two electrodes [3]. Anterior-lateral and anterior-posterior (AP) placements are both acceptable (Fig. 15.1). The anterior paddle is placed on the right infraclavicular chest. In anterior-lateral placement, the lateral paddle should be located lateral to the left breast and should have a longitudinal orientation, since this placement results in a lower transthoracic impedance than horizontal orientation. When AP positioning is used, the posterior pad is commonly located to the left of the spine at the level of the lower scapula, although some physicians favor placement to the right of, or directly over, the spine. There are data to suggest that AP placement is more successful in the cardioversion of AF
than anterior-lateral positioning when monophasic waveforms are used [13,14]. It is thought that AP positioning directs more of the delivered energy to the atria than anterior-lateral placement. However, a study employing biphasic waveforms failed to show any difference of success with anterior-lateral compared to AP pad positions [15]. It should also be noted that if a patient has an internal ICD, AP positioning is recommended to minimize the potential for damage to the device.

**FIGURE 15.1** A: Self-adhesive defibrillator pads in the anterior and lateral positions. B: Self-adhesive defibrillator pad in the posterior position. When posterior positioning is used, the second pad is placed anteriorly.

**Using the Defibrillator**

External defibrillators are designed for easy operation. After the patient is adequately prepared and the electrodes are applied, attention may be turned to the device itself. If the QRS amplitude on the rhythm tracing is small and difficult to see, a different lead should be selected. If cardioversion—rather than defibrillation—is to be performed, the synchronization function should be selected. Many defibrillators require that external leads be applied for synchronization. The appropriate initial energy is selected. Finally, the capacitor is charged, the area is cleared, and the shock is delivered. One should be aware that the synchronization function is automatically deselected after each shock in most devices, meaning that it must be manually reselected prior to any further shock delivery if another synchronized shock is desired.

**Table 15.2** provides a checklist for physicians involved in cardioversion. **Table 15.3** gives recommendations for the initial energy selection for defibrillation and cardioversion of various arrhythmias. Recommendations specific to each device are available in the manufacturer manuals and should be consulted by physicians unfamiliar with their particular device.
TABLE 15.2 Checklist for Performing External Cardioversion

Preparing the patient:
1. Ensure NPO status (6 h for solids, 2 h for clear liquids)
2. Obtain informed consent
3. Apply self-adhesive pads (clip hair if needed)
4. Apply external lead
5. Achieve adequate sedation and analgesia
6. Monitor vital signs and cardiac rhythm throughout

Performing the cardioversion:
1. Select initial energy appropriate for specific device
2. Select the synchronization function
3. Confirm that arrhythmia is still present
4. Charge, clear, and deliver shock
5. If no change in rhythm, escalate energy as appropriate

NPO, nil per os (nothing by mouth).

Treatment of Ventricular Fibrillation and Pulseless Ventricular Tachycardia
The algorithm for the treatment of pulseless VT and VF in the most recently published American Heart Association guidelines included some minor changes from the prior 2005 guidelines. A change from A-B-C to C-A-B, emphasis on “high-quality CPR” along with postcardiac arrest care, and de-emphasis of drugs and mechanical compression devices were the major updates in the 2010 guidelines [16]. “High-quality CPR” refers to minimizing interruptions in cardiopulmonary resuscitation (CPR) (especially at the time of shock delivery), adequate compression depth, and allowing for adequate chest recoil. In the 2010 algorithm, vasopressors (epinephrine or vasopressin) may be given before or after the second shock, and antiarrhythmics such as amiodarone and lidocaine may be considered before or after the third shock (Table 15.4). Both VF and pulseless VT are treated with unsynchronized, high-energy shocks of 120 to 200 J with biphasic defibrillators (or 360 J in the case of devices that use monophasic waveforms). If there is any uncertainty regarding which energy should be used, it is best to shock with the highest available energy.

| Deliver 1 shock | Monophasic: 360 J  
Biphasic: use device-specific energy; if unknown, 200 J |
| Resume compressions immediately and perform five cycles of CPR, consider advanced airway | Check rhythm—if still VT/VF, shock again  
Monophasic: 360 J  
Biphasic: same as first shock or higher dose |
| Resume compressions immediately and perform five cycles of CPR | Give a vasopressor during CPR, either before or after the second shock  
Epinephrine 1 mg IV/IO/IT, repeat every 3–5 min, OR  
Vasopressin 40 U IV/IO/IT may replace first or second dose of epinephrine |
| Check rhythm—if still VT/VF, shock again | |
Consider an antiarrhythmic before or after third shock:
- Amiodarone 300 mg IV/IO once, then consider additional 150 mg once OR
- Lidocaine 1–1.5 mg/kg first dose, then 0.5–0.75 mg/kg IV/IO, maximum three doses.

CPR, cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; IT, intratracheal; VF, ventricular fibrillation; VT, ventricular tachycardia.

Treatment of Wide Complex Tachycardia with a Pulse

When a pulse is present, a regular, wide complex tachycardia may be VT, supraventricular tachycardia with aberrant conduction, or a supraventricular tachycardia with preexcitation. If signs of instability are present (such as chest pressure, altered mental status, hypotension, or heart failure) and are thought to be secondary to the tachycardia, urgent cardioversion is indicated. A starting energy of 100 J is recommended when a monophasic shock waveform is being used. With a biphasic device, the 2010 ACLS guidelines recommend 50 to 100 J. The energy should be escalated with each successive shock.

If the patient is stable, however, one might consider enlisting the assistance of an expert in distinguishing between ventricular and supraventricular arrhythmia. If this is not possible, it is generally safest to assume a ventricular etiology. Stable VT may be treated initially with antiarrhythmic agents such as amiodarone, lidocaine, or procainamide. Elective cardioversion can be performed if necessary, once anesthesia is assured. Adenosine may also be considered for a diagnostic and therapeutic option for a regular, monomorphic, wide complex tachycardia (a new addition to the 2010 guidelines).

Irregular, wide complex tachycardia in a stable patient is probably AF with aberrant conduction; alternatively, it may represent AFL with variable AV block or multifocal AT [10]. In the unstable patient, polymorphic VT or torsades de pointes is more likely. With preexcited AF (Wolff–Parkinson–White syndrome), AV nodal blocking agents are contraindicated and treatment options include procainamide, ibutilide, or amiodarone. If the patient exhibits signs or symptoms of hypoperfusion and instability mentioned above, immediate cardioversion is advised.
Treatment of Supraventricular Tachycardia

The most common narrow complex tachycardia is sinus tachycardia which is an appropriate cardiac response to some other physiologic condition. AF and AFL are the next most common, followed by AVNRT, AVRT, and AT. Supraventricular tachycardia—defined as a non-VT other than sinus tachycardia, AF, or AFL—should be suspected when the arrhythmia starts suddenly, when it is more rapid than maximal sinus rates (220-age), and when P-waves are absent or closely follow the QRS. Initial therapy involves vagal maneuvers and adenosine. If these fail, nondihydropyridine calcium channel antagonists or β-blockers may terminate the arrhythmia. Cardioversion is indicated only rarely for clinical instability, usually in patients with underlying heart disease in whom the initial therapies fail. The recommended initial biphasic energy is 50 to 100 J.

Treatment of Atrial Fibrillation and Flutter

Rate Control

Although the majority of patients with AF and AFL remain hemodynamically stable, many develop bothersome symptoms such as palpitations, chest pressure, and, occasionally, pulmonary edema. However, a rapid ventricular response is usually secondary to, rather than the cause of, heart failure and ischemia. β-blockers, nondihydropyridine calcium channel antagonists, digoxin, amiodarone, and intravenous magnesium sulfate are used to slow the ventricular response rate by slowing AV nodal conduction [17]. Many patients become asymptomatic or minimally symptomatic with adequate rate control, allowing the decision about cardioversion to be made electively.

Electrical Cardioversion

Cardioversion for AF or AFL is usually performed electively. The risk of thromboembolism dictates a thoughtful decision about treatment options. When cardioversion is performed, an appropriate initial starting dose is 100 to 360 J for monophasic waveform shock and 120 to 200 J for biphasic shock, and higher initial energies are recommended to reduce total energy delivered and duration of sedation, especially when the AF duration is >48 hours. AFL responds to lower energy, so a starting dose
of 50 to 100 J is recommended with a monophasic waveform. The ideal starting energy for biphasic devices has not yet been defined, but should be lower than that of monophasic devices. If AF or AFL fails to terminate, shock energy should be escalated. For most defibrillators, the synchronization function must be reselected after each shock.

Anticoagulation

Patients with AF or AFL may develop thrombus in the left atrial appendage or left atrial cavity, leading to thromboembolism during or after cardioversion. One study demonstrated a risk of peri-cardioversion thromboembolism of 5.3% in patients who were not anticoagulated and 0.8% in those who were [18].

There is general agreement that cardioversion of patients who have been in AF for less than 24 to 48 hours is unlikely to cause thromboembolism, and as such, a transesophageal echocardiogram (TEE) is not required. Current guidelines indicate that peri-cardioversion anticoagulation with unfractionated heparin, low molecular weight heparin, direct thrombin inhibitor, or a factor Xa inhibitor are all acceptable options [2,19]. Individuals in AF or AFL for greater than 48 hours are at risk of thromboembolism. In these individuals, a TEE is necessary to exclude left atrial thrombus in all but the most emergent cases. Alternatively, one may anticoagulate for at least 3 weeks prior to cardioversion. It is recommended that anticoagulation continue for 3 weeks after cardioversion, as the risk of thromboembolism still exists during this period.

Pharmacologic Cardioversion

Cardioversion can be achieved not only electrically but also pharmacologically. Pharmacologic cardioversion is used mainly for AF and AFL of relatively short duration. Although electrical cardioversion is quicker and has a higher probability of success, pharmacologic cardioversion does not require sedation. The risk of thromboembolism with pharmacologic cardioversion has not been well established but is thought to be similar to that of electrical shock because it is the return of sinus rhythm rather than the shock itself that is believed to precipitate thromboembolism [5].

Dofetilide, flecainide, ibutilide, propafenone, amiodarone, and quinidine have been demonstrated to have some degree of efficacy in restoring sinus rhythm [19]. Each of these medications has potential toxicities including malignant arrhythmias and hypotension. The risks and benefits should be carefully weighed when selecting a pharmacologic agent. Although β-blockers and calcium channel antagonists are often
believed to facilitate cardioversion, their efficacy has not been established in controlled trials.

Management of Resistant Atrial Fibrillation

Although electrical cardioversion is generally successful, up to 10% of AF and AFL patients have early recurrences of arrhythmia. The duration of AF is inversely related to the probability of successful cardioversion. When cardioversion fails to even temporarily terminate the arrhythmia, the operator’s technique should be reviewed and modified. Electrode position may be altered, from AP to anterior-lateral or vice versa. Firmer pressure may be employed via the paddles or pads. If a device that delivers monophasic waveform shocks is being employed, it may be exchanged for one that delivers biphasic waveform shocks. Sotalol, ibutilide, dofetilide, or amiodarone may be initiated prior to another attempt at cardioversion. Other antiarrhythmic agents may reduce the recurrence of arrhythmia. It is worthwhile mentioning that while digoxin is useful as a rate-controlling agent, it has pro-fibrillatory effects and therefore can precipitate AF.

Complications of Defibrillation and Cardioversion

Burns

Shock can cause first-degree burns and pain at the paddle or pad site. One study documented moderate to severe pain in nearly one quarter of patients undergoing cardioversion. Pain was directly related to total energy delivered and number of shocks [20]. Another study showed a lower rate of dermal injury with biphasic rather than monophasic shocks, and is associated with lower energy necessary with biphasic shocks. The lowest effective energy should be used to minimize skin injury; however, this must be balanced against a requirement for multiple shocks when a low energy shock fails to terminate an arrhythmia. In addition, burns are much more common with self-adhesive pads, so that for elective cardioversion, paddles may be preferable.

Thromboembolism

Cardioversion of AF and AFL carries a risk of thromboembolism. Please see “Anticoagulation” section above for recommendations about prevention of thromboembolism.

Arrhythmias
Bradyarrhythmias such as sinus arrest and sinus bradycardia are common immediately after shock and are almost always short-lived. Patients who have AF may have concomitant sinus node dysfunction that is masked by the AF and unmasked by cardioversion.

VT and VF can occasionally be precipitated by shock, particularly in patients with digitalis toxicity or hypokalemia [21,22]. Elective cardioversion should therefore be avoided in patients with these conditions. If cardioversion or defibrillation must be performed urgently, one should anticipate the ventricular arrhythmias to be more refractory to shock than usual.

**Myocardial Damage**

Occasionally, one may see transient ST elevations on post-shock electrocardiograms [23] This is unlikely to signify clinically relevant myocardial injury. Although a study of cardioversion using higher-than-usual energy levels demonstrated an increase in creatine kinase-MB levels above that expected from skeletal muscle damage in 10% of patients, there was no elevation in troponin-T or -I [24]. This observation suggests that clinically significant myocardial damage from cardioversion or defibrillation is unlikely. Nonetheless, it has been suggested that any two consecutive shocks be delivered no less than 1 minute apart to minimize the chance of myocardial damage. Of course, this recommendation applies only to nonemergent situations.

**Miscellaneous Topics**

**Patients with Implanted Pacemakers and Defibrillators**

Patients with implanted pacemakers and defibrillators may undergo external cardioversion and defibrillation safely. However, one must be aware of the possibility that external energy delivery may alter the programming of the internal device. Furthermore, energy may be conducted down an internal lead, causing local myocardial injury and a resultant change (typically an increase) in the pacing or defibrillation threshold. The paddles or pads used for external electric shock should never be placed over the device. In addition, interrogation of the device immediately after any external shock delivery is recommended.

Chest Thump
The use of a manual “thump” on the chest to successfully terminate VT was described in several patients in 1970. Unfortunately, this technique may inadvertently trigger VF if the blow happens to fall during the vulnerable period of the ventricle. A chest thump is extremely unlikely to terminate VF [25]. For these reasons, chest thump is considered a therapy of last resort, administered only to a pulseless patient when a defibrillator is unavailable and unlikely to become available soon. It should not be administered when a pulse is present.

**Cardioversion and Defibrillation in Pregnancy**

Cardioversion and defibrillation have been performed in all trimesters of pregnancy without obvious adverse fetal effects or premature labor [13]. It has been suggested that the fetal heart rhythm be monitored during cardioversion [26].

INTRODUCTION

Critical care echocardiography (CCE) enables the intensivist to identify and differentiate many distinct causes of hemodynamic failure, and to initiate targeted therapy at the point of care. CCE is an essential skill for frontline intensivists and is an important component of critical care training. There is no other bedside method of cardiac imaging that is as immediate and relevant for assessment of cardiopulmonary failure. When combined with other aspects of critical care ultrasonography, it is a key element of the whole-body ultrasonography approach to the critically ill patient, because, when combined with the history and physical examination, it affords the intensivist the ability to promptly diagnose and manage hemodynamic failure. In view of the central importance of CCE, consensus statements have been published with international collaboration among critical care societies regarding competencies, training standards, and scope of practice of CCE [1–3]. This chapter reviews key aspects of both basic and advanced CCE.

Unlike the standard workflow of conventional diagnostic echocardiography as performed by or under the direction of the cardiologist, the CCE examination may be limited in scope and goal-directed; or, depending on the clinical situation and skill of the operator,
it may be as comprehensive as the consultative cardiology type examination. With CCE, the intensivist or an individual under their direction is responsible for all image acquisition and interpretation at the point of care and uses the information immediately to address specific hypotheses and to guide ongoing therapy; so the intensivist is required to have skill at image acquisition; image interpretation; and the cognitive elements required for immediate application of the results of the examination. The intensivist has full knowledge of the case, and is able to integrate the results of the CCE examination into the management plan more effectively than echocardiography performed within the constraints of the traditional echocardiography service model, where there are often delays of performance of the study; delays in interpretation; and delays of transmission of the results to the clinical team. In addition, the reader of the echocardiography service study may not be fully aware of the clinical facts of the case. Another difference with consultative echocardiography is that the CCE examination may be repeated as often as required in order to assess the effects of treatment; to follow evolution of the clinical condition; and to check for new diagnoses.

The ACCP/SRLF on Statement of Competence in Critical Care Ultrasonography was adopted as the foundation document for the International Statement on training in critical care ultrasonography that was developed and endorsed by 22 international societies [1,2]. The Competence Statement divides CCE into two parts: basic CCE and advanced CCE. These two categories require separate discussion.
BASIC CRITICAL CARE ECHOCARDIOGRAPHY

Equipment Requirements

Performance of basic CCE requires a portable machine capable of two-dimensional (2D) imaging that is equipped with a phased-array cardiac probe of frequency 2 to 5 MHz. Probes of this design have sufficient penetration for cardiac imaging, and their small footprint allows scanning between adjacent ribs. Modern portable ultrasonography machines have excellent image quality, and many have full Doppler capability, so that they are useful for both basic and advanced CCE. For basic CCE, color Doppler is recommended, but spectral Doppler (pulsed wave and continuous wave) is not mandatory, unless the machine is to be used for advanced CCE. Current generation devices that are designed to fit into pocket of the intensivist have serviceable image quality, but generally lack spectral Doppler capability. Devices available at the time of publication are suitable for basic CCE, but not for advanced CCE.

Technical Problems

Skill at transducer manipulation; optimization of machine settings; and knowledge of standard scanning planes are necessary for consistent, high-quality image acquisition. Patient positioning is an important component of image acquisition, but may be challenging in the intensive care unit (ICU). Although left arm abduction and left lateral decubitus positioning improve the quality of parasternal and apical cardiac views, optimal patient position may be difficult to achieve for all critically ill patients who may be supported with multiple life support devices; who require orthopedic immobilization; and/or who are obese. Mechanical ventilation and chronic obstructive pulmonary disease can block image acquisition owing to lung hyperinflation, and chest wall bandages and drains can limit transthoracic imaging windows. Respirophasic movement of the heart results in translational artifact, as the critically ill patient cannot suspend respiration. As a result, it may be difficult to obtain a stable tomographic plane in the dyspneic patient who has a high respiratory rate.

Training in Basic Critical Care Echocardiography

Competence for basic CCE requires mastery of three learning domains:
1. The cognitive base: The intensivist has a comprehensive knowledge of the cognitive elements of basic CCE. This includes machine operation; ultrasonography physics; cardiac anatomy; clinical applications; indications; and integration of results into other aspects of critical care ultrasonography. Resources include primary literature, review papers, textbooks, formal courses, and internet-based educational material that can be used in blended manner.

2. Image acquisition: The intensivist has definitive skill at image acquisition that includes the five standard views of basic echocardiography. Because there may be no echocardiography technician to perform the study, the quality of the images may be entirely dependent on the skill of the intensivist scanner. Competence at image acquisition is achieved by deliberate practice on normal models under the direct supervision of qualified faculty with transition to supervised scanning of critically ill patients. As the learner becomes more skilled, an autodidactic approach is effective while working with a mentor. Consensus holds that completion of a minimum of 30 acceptable quality studies is needed for competence in basic CCE [2].

3. Image interpretation: Access to a comprehensive video image collection that has a wide variety of abnormal cases provides the learner with skill at image interpretation. Image interpretation training sessions productively combine case-based learning with interpretation of the ultrasonography images. It is not reasonable to expect that the learner will, through personal scanning activity, collect sufficient examples of relevant cardiac dysfunction during their training period. This can be accomplished with a review of a well-designed image library.

Many noncardiologists have achieved competence in basic CCE. This extension of basic echocardiography competence has been supported by The American College of Echocardiography [4] and has been well documented [5–14].

As described in the ACCP/SRLF consensus statement, the basic CCE examination consists of the parasternal long-axis (PSL) view, parasternal short-axis (PSS) view, apical four-chamber (AP4) view, subcostal long-axis view, and inferior cava long-axis (IVC) view. Color Doppler may be used to assess the mitral valve (MV) and the aortic valve (AV). Although
desirable, a running ECG tracing is not required for every basic echocardiography examination. However, a running ECG tracing generally is required when performing an advanced CCE examination.

Parasternal Long-Axis View

The transducer is placed adjacent to the sternum perpendicular to the skin surface in the left third intercostal space, with the transducer index mark pointing to the right shoulder of the patient. Movement of the transducer in the caudal direction brings the parasternal long axis into view with the best image obtained in the third, fourth, or fifth intercostal space. The transducer is adjusted in small increments until the tomographic plane bisects the MV, the AV and includes the axis with the longest achievable left ventricular (LV) cavity. An optimal long-axis view displays the heart horizontally on the screen (Video of image acquisition). Patient positioning, abdominal obesity/distention, and examiner inexperience may result in a more vertical view of the heart.

Utility of the Parasternal Long-Axis View. The PSL view is used for qualitative assessment of ejection fraction (EF); right ventricular outflow tract (RVOT) and LV wall thickness and function; evaluation of AV/MV structure; evaluation of AV/MV function with screening color Doppler analysis; septal kinetics; LA chamber size; the descending aorta; and the pericardial space (Video Clips).

Pitfalls of the Parasternal Long-Axis view

1. Inability to assess RV size: The PSL view assesses the RVOT, so that it cannot be used to determine RV size. The AP4 and SCL are used for assessment of RV size.

2. Inaccurate LV size and function: Off-axis views of the LV due to rotation or angulation may lead to erroneous assessment of LV size and function. In particular, the LV may appear to be hyperdynamic with end-systolic effacement if the transducer is not orientated to identify the largest LV cavity and aligned through the midpoint of the AV and MV (Video Clips).

3. Inaccurate assessment of MV and AV function: The MV and AV may appear to be anatomically normal on 2D view, but can have substantial degrees of regurgitation, discernible only with color or spectral
Doppler analysis. Proficiency in basic CCE does not allow the examiner to reliably exclude severe valvular regurgitation. Color Doppler has limitations not intuitively obvious to the inexperienced examiner. These include gain settings (“dial a jet”); wall jet effect (Coandă effect); angle effect (both of transducer and by Doppler interrogation angle relative to the jet); and shadowing by surrounding structures such as a prosthetic valve apparatus or a calcified annulus (Video Clips).

4. Inaccurate assessment of pericardial and pleural effusion:
Identification of a pleural effusion requires that the depth setting on the ultrasound machine be increased such that the structures posterior to the heart are visualized. A pleural effusion will be seen as a relatively hypoechoic space posterior to the LV and posterior to the descending aorta. A pericardial effusion will track anterior to the descending aorta (Video Clips).

Parasternal Short-Axis Mid-Ventricular View

From the PSL long-axis view, the transducer is rotated 90° clockwise without angulation or tilting. This results in a cross-sectional view of the heart. Rotation of the transducer may be achieved using a two-handed approach accomplished by keeping the transducer steady with one hand while rotating it with the other hand. The transducer is rotated until the short axis of the heart is obtained with the transducer index mark pointing toward the left shoulder (Video of image acquisition). By angling the transducer along a right shoulder–left hip axis, multiple tomographic views of the heart may be obtained. For the basic CCE examination, the only view that is required is the mid-ventricular tomographic plane (papillary muscle level) (Video Clips).

Utility of the Parasternal Short-Axis View. The PSS view is used for qualitative assessment of EF; RV/LV wall thickness; LV segmental wall function; LV/RV chamber size and function; septal kinetics; and the pericardial space.

Pitfalls of the Parasternal Short-Axis View

1. Inaccurate assessment of LV configuration: The normal LV should be circular in short axis. An elliptical appearance results from an off-axis view related to a nonperpendicular tomographic plane or underrotation/overrotation of the transducer. An off-axis view may result in inaccurate diagnosis of systolic segmental wall abnormality or septal flattening (Video Clips). The supine position; ventilatory support with lack of diaphragmatic movement; obesity; and elevation
of intra-abdominal pressures may all cause the heart to be rotated such that the short-axis view tends to assume a more vertical position in the critically ill. This results in an off-axis view of the LV in the transverse scanning plane. This cannot be corrected by transducer manipulation. An alternative method of obtaining a short-axis view of the LV may be realized with the subcostal approach.

2. Inability to visualize the RV free wall: Estimates of RV size require visualization of the RV wall, which may be difficult in the parasternal short-axis view of the LV. The AP4 and subcostal views are superior for assessment of RV size and function.

Apical Four-Chamber View

The transducer is placed at the anatomic apex of the LV with the probe marker pointing toward the 3 to 4 o’clock position. Ideally, the patient should be placed in the left lateral decubitus position, although this is often not possible in the critically ill patient. The window for the AP4 view is often small and difficult to locate (Video of image acquisition). The septum should be oriented vertically in the center of the screen, and the tomographic plane adjusted such that it bisects the apex, the ventricles, and the atria (Video Clips).

Utility of the Apical Four-Chamber View. The AP4 view is used for qualitative assessment of EF; RV/LV wall thickness, size and function; LV segmental wall function; septal kinetics; right atrium (RA) and LA chamber size; evaluation of tricuspid valve (TV) and MV anatomy with screening color Doppler analysis; and the pericardial space.

Pitfalls of the Apical Four-Chamber View

1. Off-axis image: The AP4 view is the most difficult for the basic-level echocardiographer to obtain. There are three goals for adequate image quality. First, the position of the septum should be in the center of the screen (Video Clip). Second, the tomographic plane should bisect the anatomical apex as well as bisecting the midpoint of the MV and TV annuli (Video Clip). Finally, the transducer rotation should be adjusted such that the RV size is maximal (Video Clip). Because LV-to-RV size ratio is important measurement of basic CCE, proper orientation is important. An off-axis view may result in an inability to visualize the RV free wall, and counterclockwise transducer rotation may result in underestimation of RV size. The subcostal view is the best alternative approach, in the case of suboptimal image quality in the AP4 view position.
Subcostal Long-Axis View

This view is best obtained with the patient lying supine. The transducer is placed just below the xiphoid process, pointing toward the left shoulder. The transducer index mark is orientated to the 3 to 4 o’clock position. This view requires the transducer to be held on its top surface, because some or most of its bottom surface will be contacting the patient (Video of image acquisition). This yields a four-chamber view with the tomographic plane sectioning the heart from the right side through to the left side (Video Clip). Often the subcostal view is the best quality image of the basic CCE examination. In the hyperinflated patient on ventilatory support it may be the only obtainable image. During a cardiopulmonary resuscitation sequence, it is the preferred image plane for rapid assessment of cardiac function during short pulse checks.

Utility of the Subcostal Long-Axis View. The subcostal long-axis view is used for qualitative assessment of EF; RV/LV wall thickness, size and function; LV segmental wall function; septal kinetics; evaluation of TV/MV anatomy with screening color Doppler analysis; and the pericardial space.

Pitfalls of the Subcostal Long-Axis View

1. Off-axis view: The tomographic plane should be orientated such that the RV and LV size are maximal in size and both atria are visible. The subcostal view is particularly susceptible to translational artifact that occurs with the respiratory cycle. The heart can be pushed out of plane in patients who are in respiratory distress or on mechanical ventilatory support (Video Clips)

Inferior Vena Cava (IVC) Longitudinal View

There are several methods of obtaining the IVC longitudinal view. From the subcostal four-chamber view, the transducer is rotated counterclockwise so the index marker is in the 12 o’clock position followed by angulation of the tomographic plane toward the right (Video Clip). Alternatively, the transducer can be moved directly to a right paramedian longitudinal plane, in either subcostal or transcostal position to locate the target structure (Video Clip). If bowel gas or surgical dressings block these anterior views, the transducer should be moved to
the right mid-axillary line with the tomographic cut orientated in a coronal plane (Video Clip).

**Utility of the IVC View.** The IVC view is used for determination of volume responsiveness.

**Pitfalls of the IVC View**

1. Misidentification of the aorta as the IVC: The aorta is to the left of the midline and is posterior to the heart. The IVC is to the right of the midline, is closely associated with the liver, and passes through the diaphragm into the heart (Video Clip).

2. Off-axis view: Determination of preload sensitivity requires an accurate measurement of the IVC diameter. The scanning plane must be orientated along the longitudinal midline of the IVC to assure accurate diameter measurement (Video Clip).

3. Translational artifact: Volume responsiveness includes measurement of IVC diameter change when the patient is on ventilatory support and without spontaneous respiratory effort. When the ventilator cycles, the liver is displaced by the diaphragmatic movement. This may move the IVC out of the initial scanning plane, giving the impression of a change in diameter that actually is a translational artifact (Video Clip). This is an important consideration, because volume responsiveness may be determined by the IVC diameter change. Translational artifact may result in an inaccurate measurement of diameter change.

**Clinical Applications of Goal-Directed Echocardiography**

Basic CCE is a standard part of the evaluation of the patient with cardiopulmonary failure. Because image acquisition and interpretation is performed by or under the direction of the intensivist at the point of care, this allows the results to be immediately integrated with the history, the physical examination, and the laboratory assessment into the plan of care. By giving an immediate assessment of cardiac anatomy and function, the results influence management in a timely manner.

1. Identification of an immediately life-threatening cause for hemodynamic failure: The use of basic echocardiography allows for early identification of an imminently life-threatening process where early intervention may be lifesaving, such as pericardial tamponade; major valve failure; severe reduction in left ventricular function; or
massive pulmonary embolism. Though it is uncommon, the possibility of an immediate diagnosis of a life-threatening process justifies early basic CCE for every patient in shock (Video Clips).

2. Categorization of shock state and initial management strategy: The five standard views of basic CCE allow the intensivist to rapidly categorize shock as cardiogenic, obstructive, hypovolemic, or distributive in pattern, thereby allowing for a targeted management strategy as well as guiding the search for treatable specific causes of the hemodynamic failure (Video Clips).

3. Evolution of disease and response to therapy: Critical illness is a dynamic process, as is, often, response to therapy, so a standard aspect of basic CCE is that it is repeated in serial fashion to follow the evolution of hemodynamic failure and response to treatments. The frontline intensivist uses serial basic CCE examinations on a routine basis, with the need determined by the clinical circumstances (Video Clips).

4. Identification of coexisting diagnoses: The critically ill patient may have more than one diagnosis that may preexist or modify the acute hemodynamic phenotype. These complicating factors can occur de novo or coexist at the time of a hemodynamic insult. The basic echocardiography examination is useful to identify both the primary hemodynamic insult and important coexisting diagnoses, and clarify the best comprehensive management plan (Video Clips).

**Limitations of Basic Critical Care Echocardiography**

It is important to recognize some of the limitations of goal-directed echocardiography (GDE). Recognition of these allows the ICU team to adjust their training and scanning strategy accordingly.

1. Limited Image Set: The basic CCE examination does not replace advanced level CCE, because it is limited to five views and does not include spectral Doppler. With Doppler measurements absent, it cannot include hemodynamic measurements such as stroke volume; pulmonary artery pressures; or quantitative measurement of valvular function. A key aspect of competence in basic CCE is knowledge of when to request a full echocardiography study.

2. Failure of Image Acquisition: A major limitation of both basic and advanced CCE is inadequate image quality related to patient-specific factors such as body habitus; difficulty with positioning the patient; and respirophasic translational artifacts. In this case, TEE may be indicated.
Inadequate Training: Failure of acquisition and interpretation of adequate quality images, or lack of knowledge of clinical applications of basic CCE can derive from inadequate training. Faculty have a special responsibility to provide rigorous training in all aspects of basic echocardiography and to develop effective means of quality assessment before the trainee or technician is considered competent in basic CCE.

Challenges of Documentation: The critical care team that uses basic CCE as a primary tool for initial and serial evaluation of hemodynamic failure faces the challenge of documenting a large number of studies that are performed on a daily basis in a busy ICU. Facing this reality, basic CCE comes to resemble physical examination, where not every encounter is documented as a matter of practical necessity. This becomes problematic when trying to compare serial examinations. The solution to the challenge of documentation requires the development of methods of image storage and interpretation that can be used at the point of care. As wireless solutions become more widely available, the documentation issue will be less problematic. Integration of these data collection systems into ICU function requires training and buy-in by the intensivist staff.

Advanced Critical Care Echocardiography

Advanced CCE uses the same machine, the transducer, the image interpretation methods, and much of the same knowledge base and standard views as the cardiologist, but it differs in some ways from consultative cardiology echocardiography.

1. The examination may be as complete as the consultative cardiology examination or limited in scope. Because it is performed by the intensivist team at the point of care, the clinician decides what components of the examination are relevant given the clinical context.

2. The intensivist integrates the findings into a clinical management plan in ways that differ from consultative cardiology echocardiography, particularly when the intensivist uses advanced CCE as a hemodynamic monitoring tool. Advanced CCE is used to perform sequential examinations for patients to assess the effectiveness of changes in responses to therapy. The intensivist, in addition to having skill similar to the cardiologist in terms of diagnosis of cardiac dysfunction, also has skill at using echocardiography for sequential
assessments of hemodynamics; evolution of disease; and responses to therapies.

3. The intensivist should have skill with all aspects of image acquisition related to advanced CCE, including the full image set that is typical of consultative cardiology echocardiography with comprehensive use of Doppler measurements. As with basic CCE, the intensivist can be personally responsible for image acquisition at the point of care. This is different from the standard echocardiography model in North America, where echocardiography technicians perform the examination for subsequent interpretation by the cardiologist. This is not the case in Europe, where echocardiography technicians are not the norm. This is an evolving field with increased use of off-site real-time interpretation of images obtained by bedside caregivers or technicians.

4. Unlike the cardiologist, the intensivist who performs advanced CCE is competent in general critical care ultrasonography (thoracic ultrasonography, including lung and pleura; screening abdominal ultrasonography; and vascular study for deep venous thrombosis), so the results of advanced CCE can be productively integrated into a whole-body ultrasonography approach to assessment of critical illness.

Training in advanced CCE is not required for the majority of intensivists. Competence in advanced CCE requires a substantial course of training, so the need for it is determined by the practice requirements of the intensivist. In a large ICU with a full-time team, all team members have skill at GDE, but only a small proportion need advanced CCE skill. Based on the experience in France, where there is a well-organized training sequence for advanced CCE, between 10% and 20% of the intensivist team have training in advanced CCE, whereas the others are competent in basic CCE.

Training Requirements

The training requirements for advanced CCE are summarized in a recent consensus statement that explicitly defines the process required to become competent in image acquisition; image interpretation; and the cognitive elements of the field [3]. The document forms the basis for the requirements for certification in advanced CCE that has been developed by the European Society of Critical Care Medicine. There is possibility that a similar certification process will be developed in North America under the aegis of the National Board of Echocardiography. Important elements of advanced CCE are reviewed in Chapter 29 of this textbook, and in relevant papers [15–17] and standard textbooks.
Transesophageal Echocardiography

TEE is part of advanced CCE. TEE can be performed with a high degree of safety for the intubated patient on mechanical ventilatory support, and it has strong clinical utility particularly for post–cardiac surgery ICU patients. Its main indication is in the situation where transthoracic echocardiography results in inadequate image quality to answer the clinical question at hand. This often occurs owing to patient-specific factors (e.g., obesity, heavy musculature, and cardiac surgery), or when TTE is known to be inadequate as a scanning method (e.g., intracardiac thrombus, and evaluation for endocarditis). The European certification process for advanced CCE includes TEE as a mandatory component of the training. This reflects the fact that TEE is widely used by intensivists in Europe. The situation is different than in North America, where it is still not common for intensivists to perform TEE. At present, the North American intensivist who decides to become competent in TEE is advised to follow the training requirements used in Europe [3]. TEE simulators are an effective means of accelerating skill at image acquisition [18].

Limitations of Advanced Echocardiography

Certain aspects of echocardiography remain under the purview of the cardiology echocardiographer. These include full assessment of artificial heart valves; stress echocardiography; complex congenital heart disease; decisions related to timing of valve replacement; intraoperative assessment of valve repair/replacement; and guidance of certain cardiac procedures. It is unlikely that an intensivist would have sufficient volume of service or interest to develop competence in these applications.
REFERENCES

Pericardial diseases are commonly encountered in the critical care setting. The diagnosis and management of these disorders is challenging for physicians owing to a paucity of randomized clinical data. Pericardiocentesis offers an excellent diagnostic and therapeutic tool for the treatment of potentially life-threatening pericardial diseases. This chapter reviews the indications for emergent and urgent pericardiocentesis; summarizes the pathobiology of pericardial effusions; and provides a step-by-step approach to pericardiocentesis, including management of patients following the procedure.

INDICATIONS FOR PERICARDIOCENTESIS

The initial management of patients with a known or suspected pericardial effusion is largely determined by clinical status. In the absence of hemodynamic instability or suspected purulent bacterial pericarditis, there is no need for emergent or urgent pericardiocentesis. Diagnostic pericardiocentesis may be performed to establish the etiology of an effusion, but should be considered only after a thorough noninvasive workup has been completed [1].

Despite an extensive differential diagnosis of a new pericardial effusion, a diagnosis based on initial history and physical examination is highly predictive [2,3]. The clinical context in which diagnostic pericardiocentesis is performed affects its predictive value, with greater diagnostic yield for large effusions than for acute pericarditis [4,5]. Primarily owing to the routine use of echocardiographic guidance, the major (1.2%) and minor (3.5%) complications of pericardiocentesis have significantly decreased over the past several decades, with successful single needle passage rates approaching 90% and relief of tamponade in over 97% [6]. As a result, current guidelines recommend pericardiocentesis as the method of choice for pericardial fluid
removal/sampling [7]. Surgical intervention is recommended for recurring large effusions for which repeated pericardiocentesis has not been effective; loculated or posterior effusions of hemodynamic consequence; purulent pericarditis; traumatic hemopericardium; constrictive pericarditis; and effusions due to aortic dissection [7]. In contrast to diagnostic pericardiocentesis, the management of hemodynamically compromised patients requires emergent removal of pericardial fluid to restore adequate ventricular filling (preload) and hasten clinical stabilization. Fluid resuscitation and inotropic agents, although largely ineffective, are the mainstays of medical management that should be used only as a bridge to pericardial drainage. The method and timing of the procedure is determined by the patient’s degree of stability [8]. Although echocardiographic and fluoroscopic guidance is preferred, unguided (or blind) pericardiocentesis may be required in patients with severe hypotension not responsive to temporizing measures. In this setting, there are no absolute contraindications to the procedure, and it should be performed without delay at the patient’s bedside.

Urgent pericardiocentesis is indicated if patients are initially hypotensive but responsive to hemodynamic support. Unlike acute tamponade, subacute tamponade is more likely to present with protean symptoms such as dyspnea and fatigue. Patients with preexisting hypertension may not demonstrate severe hypotension due to a persistent sympathetic response. Echocardiographic assessment of effusion size; hemodynamic impact; and optimal percutaneous approach are of paramount importance [9]. The procedure should be performed within several hours of presentation while careful monitoring and support continue. As in elective circumstances, pericardiocentesis in these patients should be undertaken with appropriate visual guidance, the method of which depends on the physician’s expertise and resources.

Three additional points must be stressed regarding patients undergoing expedited pericardiocentesis. First, coagulation parameters—prothrombin time, partial thromboplastin time, and platelet count (>50,000/μL)—should be checked and, when possible, quickly normalized prior to the procedure. If clinically feasible, the procedure should be postponed until the international normalized ratio (INR) is less than 1.4, and an anti-Xa level is recommended for patients receiving low-molecular weight heparin. For emergent pericardiocentesis performed on anticoagulant therapy, prolonged and continuous drainage is recommended. Second, many critical care specialists advocate performance of all pericardiocentesis procedures in the catheterization laboratory with concomitant right heart pressure monitoring to document efficacy of the procedure and to exclude a constrictive element of pericardial disease, although excessive delays must be avoided. Finally,
efforts to ensure a cooperative and stationary patient during the procedure greatly facilitate the performance, safety, and success of pericardiocentesis.
ANATOMY

The clinical presentation of pericardial effusion is greatly influenced by pericardial anatomy and physiology. The pericardium is a membranous structure with two layers: the visceral and parietal pericardium. The visceral pericardium is a monolayer of mesothelial cells adherent to the epicardial surface by a loose collection of small blood vessels, lymphatics, and connective tissue. The parietal pericardium is a relatively inelastic 2 mm-dense outer network of collagen and elastin with an inner surface of mesothelial cells. It is invested around the great vessels and defines the shape of the pericardium, with attachments to the sternum, diaphragm, and anterior mediastinum while anchoring the heart in the thorax [10]. Posteriorly, the visceral epicardium is absent, with the parietal epicardium attached directly to the heart at the level of the vena cavae [11]. The potential space between the visceral and parietal mesothelial cell layers normally contains 15 to 50 mL of serous fluid in the AV and interventricular grooves, which is chemically similar to plasma ultrafiltrate [12]. The pericardium is relatively avascular, but is well innervated and may produce significant pain with vagal responses during procedural manipulation or inflammation [13].

Owing to the inelastic physical properties of the parietal pericardium, the major determinant of when and how pericardial effusions come to clinical attention is directly related to the speed of accumulation. Effusions that collect rapidly (over minutes to hours) may cause hemodynamic compromise with volumes of 250 mL or less. These effusions are usually located posteriorly and are often difficult to detect without echocardiography or other imaging modalities such as multislice computed tomography (CT) or cardiac magnetic resonance imaging (MRI). In contrast, effusions developing slowly (over days to weeks) allow for dilation of the fibrous parietal membrane. Volumes of 2,000 mL or greater may accumulate without significant hemodynamic compromise. As a result, chronic effusions may present with symptoms owing to compression of adjacent thoracic structures such as cough, dyspnea, dysphagia, or early satiety. Conversely, intravascular hypovolemia; impaired ventricular systolic function; and ventricular hypertrophy with decreased elasticity of the myocardium (diastolic dysfunction) may exacerbate hemodynamic compromise without significant effusions present evident by imaging methods.
Effusive-constrictive pericarditis (up to 7% of patients with tamponade) results from the accumulation of fluid between the visceral and parietal pericardium and may be transient (chemotherapy) or persistent. This diagnosis is important to make owing to its likelihood to evolve into a persistent constriction [14]. It is defined as failure of the right atrial pressure to decrease by more than 50% or to <10 mm Hg after pericardiocentesis as well as persistent signs of constriction on right heart catheter and on physical exam. Like most effusions, the clinical course is determined by the underlying etiology, but if symptoms of right heart failure persist, a visceral pericardectomy must be performed.
PROCEDURE

Since the first blind (or closed) pericardiocentesis performed in 1840 [15], numerous approaches to the pericardial space have been described. Marfan [16] performed the subcostal approach in 1911, which then became the standard approach for unguided pericardiocentesis, because it is extrapleural and avoids the coronary and internal mammary arteries.

The advent of clinically applicable ultrasonography has opened a new chapter in diagnostic and therapeutic approaches to pericardial disease, allowing clinicians to quantitate and localize pericardial effusions quickly and noninvasively [17–21]. Callahan et al. [22] at the Mayo Clinic established the efficacy and safety of two-dimensional (2D) echocardiography to guide pericardiocentesis. Although direct quantification of total fluid accumulation with echo is difficult, circumferential effusions >10 mm are considered large (500 mL), and guidelines recommend pericardiocentesis for effusions >20 mm, regardless of the presence of hemodynamic compromise [7]. Typically, at least 250 mL of fluid is required for safe pericardiocentesis. The routine use of echocardiography has resulted in two major trends in clinical practice: First, 2D echocardiography is commonly used to guide pericardiocentesis, with success rates comparable to traditionally fluoroscopic guided procedures [19,23–25]. Second, approaches other than the traditional subxiphoid method have been investigated owing to the ability to clearly define the anatomy (location and volume) of each patient’s effusion [22]. In one series of postsurgical patients, the subxiphoid approach was the most direct route in only 12% of effusions [26]. With the use of echocardiographic guidance, apical and parasternal pericardiocentesis are increasingly performed with comparable success rates to the subxiphoid approach. In the apical approach, the needle is directed parallel to the long axis of the heart toward the aortic valve. Parasternal pericardiocentesis is performed with needle insertion 1 cm lateral to the sternal edge, to avoid internal mammary laceration. All approaches employ a Seldinger technique of over-the-wire catheter insertion. Because the subxiphoid approach remains the standard of practice and is the preferred approach for unguided emergent pericardiocentesis, it is described below.

Regardless of the approach used, confirmation of appropriate positioning is mandatory and preferably performed before a dilation catheter is advanced over the wire. Direct visualization of the needle with either echocardiography or fluoroscopy and injection of agitated saline (echo-guided) contrast (fluoroscopy-guided) should be performed to confirm the correct position [21].
In addition to two large-bore peripheral intravenous lines for aggressive resuscitative efforts, standard electrocardiographic monitoring is mandatory. Historically, an electrocardiogram (ECG) lead directly attached to the puncture needle has been used to detect contact with the myocardium via the appearance of a large “injury current” (ST elevation). Owing to the fact that a suboptimally grounded needle could fibrillate the heart (and the widespread availability of echocardiography), it is considered an inadequate safeguard [7].

The materials required for bedside pericardiocentesis are listed in Table 17.1. Table 17.2 lists the materials required for simultaneous placement of an intrapericardial drainage catheter. The materials are available in prepackaged kits or individually (Figures 17.1 and 17.2).

FIGURE 17.1 Materials required for pericardiocentesis (clockwise from upper left): 1% lidocaine solution; suture material; 10-mL syringe with 25-gauge needle; 10-mL syringe with 22-gauge needle; no. 11 blade; 18-gauge 8-cm thin-walled needle; 20-mL syringe; 30-mL syringe; alligator clip; hemostat; three red-top tubes; two purple-top tubes; culture bottles; and scissors.
The subxiphoideal approach for pericardiocentesis is as follows:

1. Patient preparation: Assist the patient in assuming a comfortable supine position with the head of the bed elevated to approximately 45 degrees from the horizontal plane. Extremely dyspneic patients may need to be positioned fully upright, with a wedge if necessary. Elevation of the thorax allows free-flowing effusions to collect inferiorly and anteriorly, the sites that are safest and easiest to access using the subxiphoid approach.
2. Needle entry site selection: Locate the patient’s xiphoid process and the border of the left costal margin using inspection and careful palpation. The needle entry site should be 0.5 cm to the (patient’s) left of the xiphoid process and 0.5 to 1.0 cm inferior to the costal margin (Fig. 17.3). It is helpful to estimate (by palpation) the distance between the skin surface and the posterior margin of the bony thorax. This helps guide subsequent needle insertion. The usual distance is 1.0 to 2.5 cm, increasing with obesity or protuberance of the abdomen.

3. Site preparation: Strict sterile techniques must be maintained at all times in preparation of the needle entry site. Prepare a wide area in the subxiphoid region and lower thorax with a povidone–iodine or alcohol chlorhexidine solution and drape the field with sterile towels, leaving the subxiphoid region exposed. After a time-out, raise a 1- to 2-cm subcutaneous wheal by infiltrating the needle entry site with 1% lidocaine solution (without epinephrine). To facilitate needle entry, incise the skin with a No. 11 blade at the selected site after achieving adequate local anesthesia.

4. Insertion of the needle apparatus: The angle of entry with respect to the skin should be approximately 45 degrees in the subxiphoid area. Direct the needle tip superiorly, aiming for the patient’s left shoulder. Continue to advance the needle posteriorly while alternating between aspiration and injection of lidocaine (with a half-filled 20 mL syringe of 1% lidocaine), until the tip has passed just beyond the posterior border of the bony thorax (Fig. 17.4). The posterior border usually lies within 2.5 cm of the skin surface. If the needle tip contacts the bony thorax, inject lidocaine after aspirating to clear the needle tip and anesthetize the periosteum. Then, walk the needle behind the posterior (costal) margin.

5. Needle direction: Once under the costal margin, reduce the angle of contact between the needle and skin to 15 degrees: This will be the angle of approach to the pericardium; the needle tip, however, should still be directed toward the patient’s left shoulder. A 15-degree angle is used regardless of the height of the patient’s thorax (whether at 45 degrees or sitting upright) (Fig. 17.5).

6. Needle advancement: Advance the needle slowly while alternating between aspiration of the syringe and injection of 1% lidocaine solution. Obtain a baseline lead V tracing and monitor a continuous ECG tracing for the presence of ST-segment elevation or premature ventricular contractions (evidence of epicardial contact) as the needle is advanced. Advance the needle along this extrapleural path until either:

a. A “give” is felt, and fluid is aspirated from the pericardial space
(usually 6.0 to 7.5 cm from the skin) (Fig. 17.6). Some patients may experience a vasovagal response at this point and require atropine intravenously to increase their blood pressure and heart rate.

b. ST-segment elevation or premature ventricular contractions are observed on the electrocardiographic lead V tracing when the needle tip contacts the epicardium. If ST-segment elevation or premature ventricular complexes occur, immediately (and carefully) withdraw the needle toward the skin surface while aspirating. Avoid any lateral motion, which could damage the epicardial vessels. Completely withdraw the needle if no fluid is obtained during the initial repositioning.

If a sanguineous fluid is aspirated, the differentiation between blood and effusion must be made immediately. In addition to confirming catheter position by saline, contrast, or pressure transduction, several milliliters of fluid can be kept and observed for clotting. Intrinsic fibrinolytic activity in the pericardium prevents subacute/chronic effusions from clotting, where frank hemorrhage or intraventricular blood will overwhelm fibrinolysis.

The patient’s hemodynamic status should improve promptly with removal of sufficient fluid. Successful relief of tamponade is supported by (a) a fall of intrapericardial pressure to levels between −3 and +3 mm Hg, (b) a fall in right atrial pressure and a separation between right and left ventricular diastolic pressures, (c) augmentation of cardiac output, (d) increased systemic blood pressure, and (e) reduced pulsus paradoxus to physiologic levels (10 mm Hg or less). An improvement may be observed after removal of the first 50 to 100 mL of fluid. If the right atrial pressure remains elevated after fluid removal, an effusive-constrictive process should be considered. The diagnostic studies performed on pericardial fluid are outlined in Table 17.3. Several options exist for continued drainage of the pericardial space. The simplest approach is to use large-volume syringes and aspirate the fluid by hand. This approach is not always practical (i.e., in large-volume effusions), and manipulation of the needle apparatus may cause myocardial trauma. Alternatively, most pericardiocentesis kits include materials and instructions for a catheter-over-needle technique for inserting an indwelling pericardial drain via the Seldinger technique.

7. Pericardial Drain Placement: Create a tract for the catheter by passing a 6 French (Fr) dilator over a firmly held guidewire. After removing the dilator, use the same technique to pass an 8 Fr dilator. Then advance an 8 Fr flexible pigtail (or side hole) catheter over the guidewire into the pericardial space. Remove the guidewire. Passage of the dilators is facilitated by use of a torquing
Proper positioning of the catheter using radiography, fluoroscopy, or bedside echocardiography can be used to facilitate fluid drainage.

3. Drainage system [27,28]: Attach a three-way stopcock to the intrapericardial catheter and close the system by attaching the stopcock to the sterile collecting bag with the connecting tubing. The catheter may also be connected to a transducer, allowing intrapericardial pressure monitoring. The system may be secured as follows:

   a. Suture the pigtail catheter to the skin, making sure that the lumen is not compressed. Cover the entry site with a sterile gauze and dressing.

   b. Secure the drainage bag (or bottle) using tape at a level approximately 35 to 50 cm below the level of the heart. Echocardiography or fluoroscopic guidance may be used to reposition the pigtail catheter, facilitating complete drainage of existing pericardial fluid.

      It is recommended to drain fluid in sequential steps of <1,000 mL to avoid acute right-ventricular dilation—a rare but serious complication [7,29]. Drainage is recommended until pericardial pressure is subatmospheric with inspiration. The catheter should be flushed manually every 4 to 6 hours using 10 to 15 mL of normal saline solution until volume of aspiration falls to <25 mL per day [30].
FIGURE 17.3 Selected locations for pericardiocentesis. In most cases, the subxiphoid approach (1 to 3) is preferred. (From Spodick DH: Acute Pericarditis. New York, Grune & Stratton, 1959, with permission.)

FIGURE 17.4 Insertion of the needle apparatus. After the subxiphoid region and lower thorax are
prepared and adequate local anesthesia is given, the pericardiocentesis needle is inserted in the subxiphoid incision. The angle of entry (with the skin) should be approximately 45 degrees. The needle tip should be directed superiorly, toward the patient's left shoulder.

**FIGURE 17.5** Needle direction. The needle tip should be reduced to 15 degrees once the posterior margin of the bony thorax has been passed. Needle advancement: The needle is advanced toward the left shoulder slowly while alternating between aspiration and injection. A “give” is felt, and fluid is aspirated when the pericardial space is entered.
FIGURE 17.6 Placement technique. Holding the needle in place, a Teflon-coated, 0.035-inch guidewire is advanced into the pericardial space. The needle is then removed. After a series of skin dilations, an 8 Fr, 35-cm flexible pigtail catheter is placed over the guidewire into the pericardial space. Passage of dilators and the pigtail catheter is facilitated by a gentle clockwise/counterclockwise motion.

SHORT-TERM AND LONG-TERM MANAGEMENT

After pericardiocentesis, close monitoring is required to detect evidence of recurrent tamponade and procedure-related complications. Table 17.4 lists the most common serious complications associated with pericardiocentesis [1,7,31,32]. Factors associated with an increased risk of complications include (a) small effusion (less than 250 mL), (b) posterior effusion, (c) loculated effusion, (d) maximum anterior clear space (by echocardiography) less than 10 mm, and (e) unguided percutaneous approach. All patients undergoing pericardiocentesis should have a portable chest radiograph after the procedure to exclude the presence of pneumothorax. A transthoracic 2D echocardiogram should be obtained within several hours to evaluate the adequacy of pericardial drainage and confirm catheter placement. Because pericardiocentesis typically does not remove all of the effusion (and active bleeding or secretion may occur), the pericardial catheter is typically left in place for 24 to 72 hours or until drainage subsides. Extended catheter drainage is safe, and is associated with a trend toward lower recurrence rates over a 4-year follow-up [30]. Catheter drainage of >100 mL per day after 3 days should prompt consideration of surgical intervention, sclerosing agents, or percutaneous balloon pericardotomy.

\(^a\)Incidence has varied from 0\% to 5\% in studies and was less common in guided procedures, more common in “blind” procedures.

The long-term management of patients with significant pericardial fluid collections is beyond the scope of this chapter; however, the indications for surgical intervention are reviewed briefly above. The etiology of the pericardial effusion (Table 17.5), and the patient’s functional status are of central importance for determining the preferred treatment. Aggressive attempts at nonsurgical management of chronically debilitated patients or those with metastatic disease involving the pericardium may be appropriate [33,34]. Percutaneous balloon pericardotomy or pericardial sclerosis with tetracycline, cisplatin, and other agents has benefited carefully selected patients with malignant pericardial disease [35–37]. Patients with a guarded prognosis who fail aggressive medical therapy should be offered the least invasive procedure.

Utility of Ultrasonography for Management of Pericardial Effusion

Ultrasonography has several useful applications related to the management of pericardial effusion.

1. Identification of Pericardial Fluid
   Pericardial fluid is readily identified by echocardiographic examination. The pericardial space is, in health, a virtual space that contains no fluid. Fluid accumulation in the pericardial space is hypoechoic and defined by the anatomic boundaries of the pericardium. Using the standard five-view basic echocardiography examination sequence (See Chapter 16 on Critical Care Echocardiography), pericardial fluid can be readily identified and characterized. Small pericardial effusions are visualized posterior to the heart in the parasternal long-axis and short-axis, and subcostal long-axis views of the heart. When moderate or large in volume, the effusion surrounds the heart, and is visible in the apical four-chamber view (Chapter 17 Video 17.1). Pericardial fluid is often hypoechoic, but infection or malignancy may result in increased echogenicity, stranding, septations, or masses within the fluid (Chapter 17 Video 17.2).

   Pericardial fluid is readily identified with transesophageal echocardiography (TEE) (Chapter 17 Video 17.3). With TEE, the pericardial space extends to the base of the heart in a series of complex reflections that are visible when distended with fluid. These may cause confusion, if misidentified by the inexperienced examiner. A specific
application of TEE is for identification of loculated pericardial effusions post–cardiac surgery that may cause local pericardial tamponade due to chamber compression (Chapter 17 Video 17.3). These may not be visible with transthoracic echocardiography. Unexplained hypotension in the post–cardiac surgery patient requires TEE to rule out this potentially lethal complication.

Anterior pericardial fat may be mistaken for pericardial fluid. Pericardial fat has hyperechoic elements within it that move with cardiac contraction. The absence of a coexisting posterior effusion favors anterior pericardial fat. In the parasternal long-axis view, pleural effusion may be confused with pericardial fluid. Pericardial fluid distributes anterior to the descending aorta on the parasternal long-axis view, whereas pleural fluid is posterior to the aorta (Chapter 17 Video 17.4).

2. Assessment for Pericardial Tamponade

2D echocardiography is useful for identifying findings consistent with pericardial tamponade (Chapter 17 Video 17.5). Chamber collapse is suggestive, but not diagnostic of tamponade physiology. It is useful to have an ECG tracing on the ultrasonography screen in order to accurately time any chamber collapse. Right atrial (RA) collapse is best seen from the apical four-chamber and subcostal long-axis view. Normally, the right atrium should fill during systole, so the finding of a systolic RA collapse is abnormal. Early diastolic collapse of the right atrium is sensitive for tamponade. High RA pressures and severe tricuspid regurgitation may mask RA collapse.

Right ventricular (RV) collapse is best seen from the parasternal short and subcostal long-axis views. The right ventricle fills during diastole, so a collapse of the right ventricle during diastole is abnormal. The collapse of the RV outflow track (RVOT) occurs before the RV free wall is involved, owing to the fact the RVOT is a thinner-walled structure. The RVOT is best imaged from the parasternal long-axis view, whereas the RV free wall is best imaged from the apical four-chamber and subcostal long-axis views. High right-sided pressures and RV wall hypertrophy may mask RV collapse. The presence of chamber compression does not in itself indicate that there is tamponade physiology, nor does its absence rule it out.

The presence of a swinging heart within large pericardial effusion is suggestive of pericardial tamponade, as is respirophasic variation of chamber size on M-mode obtained with the sample line placed through the right ventricle and left ventricle from the parasternal long-axis view. Pericardial tamponade predictably results in distention of the inferior vena cave (IVC). The presence of a small IVC makes pericardial tamponade very unlikely. Doppler echocardiography has utility for assessment for pericardial tamponade. A characteristic
feature of tamponade physiology is respirophasic variation of stroke volume (SV) owing to accentuation of ventricular interdependence. This is manifested with respirophasic variation of mitral valve and tricuspid valve diastolic inflow velocities. A greater than 30% respirophasic variation of mitral valve E wave velocity is characteristic of pericardial tamponade measured from the apical four-chamber view. Respirophasic variation of SV is measured in the LVOT from the apical five-chamber view and represents the echocardiographic equivalent of paradoxical pulse.

Doppler analysis has limitations. It requires advanced level training and is time-consuming for the frontline intensivist. Major variation of intrathoracic pressure, such as that occurs with airway obstruction due to asthma or upper airway obstruction, causes respirophasic variation of SV. Translational artifact due to respirophasic movement of the heart may cause changes in Doppler signal that are unrelated to SV variation.

Both 2D and Doppler echocardiography are helpful in identifying the patient with pericardial tamponade. Because there are sufficient confounders, echocardiographic findings, though helpful, should never be considered diagnostic. Pericardial tamponade remains a clinical diagnosis that may or may not be supported by echocardiographic findings.

Guidance of Pericardiocentesis

Ultrasonography is the preferred method for safe performance of pericardiocentesis when compared to fluoroscopic guidance. Seward et al. described 1,127 serial pericardiocenteses performed with ultrasonographic guidance with a very low complication rate [25]. Guidance with fluoroscopy is performed using the subcostal approach. Because fluoroscopy is a 2D imaging technique, the position of the liver; the relationship of the needle to the myocardium; and the relationship of the lung to the needle trajectory is less certain than with ultrasonography imaging.

Pericardiocentesis performed with ultrasonographic guidance uses the same principles as those of thoracentesis and paracentesis. The fluid collection is identified, and the operator determines a safe site, angle, and depth for needle insertion while avoiding injury to adjacent anatomic structures. The operator needs to be skilled at image acquisition and interpretation, because an injury to the myocardium or coronary artery is a catastrophic complication of pericardiocentesis (Chapter 17 Video 17.6).
Site Selection and Preparation

- Using ultrasonography, the best site is determined by where the most fluid is found. This may be at any point on the anterior or lateral chest or from the subcostal view. The best site is often found on the lateral chest using the apical four-chamber view (Chapter 17 Video 17.6). If the effusion is very large, the parasternal view may offer a good approach. When the effusion is predominately posterior in location, changing the patient’s body position may distribute the fluid into a more favorable position. The left lateral decubitus position may shift the fluid for an improved apical view, whereas a semisupine position may improve the subcostal view.

- The distance between the site of needle penetration into the pericardium and the heart is an important determinant of safety. The heart changes in size throughout the contractile cycle; cardiac “swinging” is a common phenomenon in severe tamponade, and the respirophasic translational movement of the heart is accentuated during the respiratory cycle. As a result, the thickness of the pericardial effusion may change a major extent during cardiac movement. A reasonable approach is to require at least 1 cm of fluid depth between the heart and the planned needle entry point into the pericardial fluid.

- An important element in safe site selection is the avoidance of injury to adjacent structures. The lung is of concern. Fortunately, aerated or consolidated lung is easy to identify and therefore easy to avoid (see Chapter 11 on Lung Ultrasonography). The liver is readily identified, and therefore avoided when considering the subcostal approach. Color Doppler examination of the planned needle trajectory is mandatory when using the parasternal approach, in order to avoid the internal mammary vessels. A pleural effusion may occur concomitantly with the pericardial effusion, and may block access to the pericardial fluid. In this situation, it is best to drain the pleural effusion, and then to determine the best approach to the pericardial effusion. Occasionally, ascites may be mistaken for pericardial effusion in the subcostal long-axis view.

- The best site and angle for needle insertion is determined, and the site is marked. Using the calipers function, the depth of needle penetration is measured from a frozen image on the ultrasound screen. Before obtaining a final confirmatory scan, equipment setup should be complete. This reduces the period between the final scan and needle insertion, thereby allowing the operator to maintain recent memory of the angle of approach during needle insertion. Following sterile skin preparation, the patient is covered with a full
body drape. The transducer with sterile sleeve is part of the field setup, thereby allowing scanning during the procedure, because the operator may choose to reconfirm site, depth, and angle for needle insertion following sterile site preparation. The angle of needle insertion for device insertion duplicates the angle of probe angle that identified the safe trajectory for needle insertion.

- The operator proceeds with needle–wire insertion, followed by catheter insertion. Confirmation of wire or catheter insertion may be accomplished by direct visualization using 2D ultrasonography. If there is a question of proper position, several milliliters of agitated saline may be injected through the catheter to document catheter position.

- Similar to thoracentesis and paracentesis, pericardiocentesis does not require real-time guidance with ultrasonography. The largest published study [25] on the subject did not use real-time guidance. However, it is important to have the transducer with sterile cover in place for immediate use throughout the procedure, in case there is a need to rescan and document successful device insertion.

### Pitfalls: Common and Uncommon

- Skin compression artifact is a common problem, because it may cause an underestimation of the depth for needle insertion. This occurs in the obese or edematous patient when the operator pushes the probe into the skin while searching for a safe needle insertion site. Measurement of needle insertion distance is made while compressing the skin and underlying soft tissue. On removal of the probe pressure, the skin rebounds, such that the needle insertion is underestimated. During actual needle insertion, the operator is appropriately concerned, if there is no fluid obtained at the depth measured from the ultrasound machine screen. The solution to this problem is to rescan the patient, confirm the angle of insertion, and estimate the compression artifact more accurately. Another cause for difficulty is movement of the mark that designates the appropriate site for needle insertion. Skin is movable, so the injudicious application of force by the operator’s hand may shift the skin mark. The needle should be inserted at the mark without any tension applied to the area that might shift the mark position. Similarly, a “dry tap” might result from inaccurate duplication of the angle at which the transducer was held, or an inaccurate skin mark. The solution remains to rescan the patient to recheck the angle and site. Generally, it is easier to duplicate a perpendicular transducer angle than one that is acutely angled. This favors an anterior or lateral chest wall approach (if fluid is accessible), because the transducer is often perpendicular to the
chest wall when scanning in these areas. This is not the case in the subcostal approach.

- An unusual cause of a “dry tap” is a blocked needle, resulting from an overly deep needle insertion. Clotted blood or skin plug may be the culprit. Overly vigorous probing of the anterior costal cartilage (if using a parasternal approach) may also block the needle with cartilage, causing the operator to insert the needle too deeply, with potential complications to the patient.

- A large anterior pericardial fat pad may be mistaken for a pericardial effusion by the inexperienced ultrasonographer. Pericardial fat has some element of echogenicity and moves in synchrony with cardiac contraction. However, it is very uncommon for a consequent pericardial effusion to occur anterior to the heart without a significant posterior pericardial effusion also being present.

- An uncommon pitfall of pericardiocentesis occurs when the anesthesia needle penetrates the pericardium after having traversed a pleural effusion. The pericardial effusion may then drain into the pleural space through the defect in the pericardium made by the anesthesia needle. This may occur if there is a delay before definitive pericardial device insertion. The operator is unpleasantly surprised by the lack of pericardial effusion, and the presence of a new pleural effusion. To avoid this situation, device insertion should promptly follow infiltration of the local anesthesia.
SUMMARY

Ultrasonography permits safe pericardiocentesis. Ultrasonography allows the intensivist to select a safe site, angle, and depth for needle and device insertion. Careful attention to image acquisition and interpretation allows the operator to avoid the serious complication of myocardial or coronary artery laceration. The critical care ultrasonographer is strongly encouraged to develop proficiency in ultrasound guidance of pericardiocentesis, because it is superior to subcostal fluoroscopic guidance.
REFERENCES

Infarct 15:529, 1911.

Temporary cardiac pacing may be urgently required for the treatment of cardiac conduction and rhythm disturbances seen in the intensive care unit (ICU). Therefore, ICU personnel should be familiar with the indications and techniques for initiating and maintaining temporary cardiac pacing, as well as the possible complications of this procedure. Recommendations for training in the performance of transvenous pacing have been published by a Task Force of the American College of Physicians (ACC), American Heart Association (AHA), and American College of Cardiology (ACC) [1]. Competence in the performance of transvenous pacing also requires the operator to have training in central venous access (Chapter 6) and hemodynamic monitoring (Chapter 28) [2].

INDICATIONS FOR TEMPORARY CARDIAC PACING

As outlined in Table 18.1, temporary pacing is indicated in the diagnosis and management of a number of serious rhythm and conduction disturbances.

<table>

left bundle branch block, first-degree AV block), or alternating left and right bundle branch block complicating acute anterior myocardial infarction

3. Symptomatic idiopathic third-degree AV block, or high-degree AV block

B. Rate disturbances

1. Hemodynamically significant or symptomatic sinus bradycardia
2. Bradycardia-dependent ventricular tachycardia
3. AV dissociation with inadequate cardiac output
4. Polymorphic ventricular tachycardia with long QT interval (torsades de pointes)
5. Recurrent ventricular tachycardia unresponsive to medical therapy

AV, atrioventricular.

Bradyarrhythmias

The most common indication for temporary pacing in the ICU setting is a hemodynamically significant or symptomatic bradyarrhythmia such as sinus bradycardia or high-grade atrioventricular (AV) block.

Sinus bradycardia and AV block are commonly seen in patients with acute coronary syndromes, hyperkalemia, myxedema, or increased intracranial pressure. Infectious processes such as endocarditis or Lyme disease may impair AV conduction. Bradyarrhythmias also result from treatment or intoxication with digitalis, antiarrhythmic, β-blocker, or calcium channel blocker medications, and may also result from exaggerated vasovagal reactions to ICU procedures such as suctioning of the tracheobronchial tree in the intubated patient. Bradycardia-dependent ventricular tachycardia may occur in association with ischemic heart disease.

Tachyarrhythmias

Temporary cardiac pacing is used less often for the prevention and termination of supraventricular and ventricular tachyarrhythmias. Atrial pacing in the ICU setting is often performed when temporary
epicardial electrodes have been placed during cardiac surgery. Pacing termination of atrial flutter in cardiac surgery patients with epicardial leads may be preferable to synchronized cardioversion, which carries the risk associated with sedation. A critical pacing rate (usually 125% to 135% of the flutter rate) and pacing duration (usually about 10 seconds) are important in the successful conversion of atrial flutter to sinus rhythm [3].

Temporary pacing may be required for the prevention of paroxysmal polymorphic ventricular tachycardia in patients with prolonged QT intervals (torsades de pointes), particularly when secondary to drugs [4,5]. Temporary cardiac pacing with a mild tachycardia is the treatment of choice to stabilize the patient while a type I antiarrhythmic agent exacerbating ventricular irritability is metabolized. The effectiveness of cardiac pacing probably relates to decreasing the dispersion of refractoriness of the ventricular myocardium (shortening the QT interval).

Temporary ventricular pacing may be successful in terminating ventricular tachycardia. If ventricular tachycardia must be terminated urgently, cardioversion is mandated (Chapter 15). However, in less urgent situations, conversion of ventricular tachycardia via rapid ventricular pacing may be useful. “Overdrive” ventricular pacing is often effective in terminating monomorphic ventricular tachycardia in a patient with remote myocardial infarction or in the absence of heart disease. This technique is less effective when ventricular tachycardia complicates acute myocardial infarction or cardiomyopathy. Rapid ventricular pacing is most successful in terminating ventricular tachycardia when the ventricle can be “captured” (asynchronous pacing for 5 to 10 beats at a rate of 50 beats per minute greater than that of the underlying tachycardia). A cardiac defibrillator should be immediately available, because pacing may result in acceleration of ventricular tachycardia or degeneration to ventricular fibrillation.
Diagnosis of Rapid Rhythms

Temporary atrial pacing electrodes may be helpful for the diagnosis of tachyarrhythmias when the morphology of the P wave and its relation to the QRS complexes cannot be determined from the surface electrocardiogram (ECG) [6]. A recording of the atrial electrogram is helpful in a regular, narrow-complex tachycardia in which the differential diagnosis includes atrial flutter, AV node reentry, or other supraventricular rhythm. This technique may also assist in the diagnosis of wide-complex tachycardias in which the differential diagnosis includes supraventricular tachycardia with aberrant conduction; sinus tachycardia with bundle branch block; and ventricular tachycardia.

To record an atrial ECG, the ECG limb leads are connected in the standard fashion, and a precordial lead (usually V₁) is connected to the proximal electrode of the atrial pacing catheter or to an epicardial atrial electrode. A multichannel ECG rhythm strip is run at a rapid paper speed, simultaneously demonstrating surface ECG limb leads as well as the atrial electrogram obtained via lead V₁. This rhythm strip should reveal the conduction pattern between atria and ventricles as antegrade, simultaneous, retrograde, or dissociated.
ACUTE MYOCARDIAL INFARCTION

Sinus node dysfunction, disorders of AV conduction and disorders of intraventricular conduction may occur in the acute stages of an infarction [7]. Recommendations for temporary cardiac pacing have been provided by a Task Force of the ACC and the AHA (Table 18.2) [8]. Bradyarrhythmias unresponsive to medical treatment that result in hemodynamic compromise or symptoms require urgent treatment. Patients with anterior infarction and bifascicular block or Mobitz type II second-degree AV block, though hemodynamically stable, are at risk for development of complete heart block with an unstable escape rhythm and should be considered for a temporary pacemaker [9].

This table is designed to summarize the AV (column headings) and intraventricular (row headings) conduction disturbances that may occur during acute anterior or nonanterior STEMI, the possible treatment options, and the indications for each possible therapeutic option.

ACC/AHA, American College of Cardiology/American Heart Association; LAFB, left anterior fascicular block; LPFB, left posterior fascicular block; RBBB, right bundle-branch block; BBB, bundle-branch block; OB, observe; A, atropine; TC, transcutaneous pacing; TV, temporary transvenous pacing; STEMI, ST elevation myocardial infarction; AV, atrioventricular; MI, myocardial infarction; AMI, anterior myocardial infarction; nonAMI, non-anterior myocardial infarction.

**Action:** There are four possible actions, or therapeutic options, listed and classified for each bradyarrhythmia or conduction problem:

1. Observe: continued ECG monitoring, no further action planned.
2. A, and A*: atropine administered at 0.6 to 1.0 mg IV every 5 minutes to up to 0.04 mg per kg. In general, because the increase in sinus rate with atropine is unpredictable, this is to be avoided unless there is symptomatic bradycardia that will likely respond to a vagolytic agent, such as sinus bradycardia or Mobitz I, as denoted by the asterisk, above.
3. TC: application of transcutaneous pads and standby transcutaneous pacing with no further progression to transvenous pacing imminently planned.
4. TV: temporary transvenous pacing. It is assumed, but not specified in the table, that at the discretion of the clinician, transcutaneous pads will be applied and standby transcutaneous pacing will be in effect as the patient is transferred to the fluoroscopy unit for temporary transvenous pacing.

**Class:** Each possible therapeutic option is further classified according to ACC/AHA criteria as Class 1: indicated, 2A: probably indicated, 2B: possibly indicated, and 3: not indicated.

**Level of Evidence:** This table was developed from published observational case reports and case series,
published summaries, not meta-analyses, of these data; and expert opinion, largely from the prererefusion era. There are no published randomized trials comparing different strategies of managing conduction disturbances after STEMI. Thus, the level of evidence for the recommendations in this table is C.

How to Use the Table: Example: A 54-year-old man is admitted with an anterior STEMI and a narrow QRS on admission. On day 1, he develops a right bundle-branch block (RBBB), with a PR interval of 0.28 seconds.

1. RBBB is an intraventricular conduction disturbance, so look at row ‘New bundle-branch block.’
2. Find the column for “First-Degree AV Block.”
3. Find the “Action” and “Class” cells at the convergence.
4. Note that “Observe” and “Atropine” are class 3, not indicated; transcutaneous pacing (TC) is class 1. Temporary transvenous pacing (TV) is class 2B.

From ref. [28] with permission. Copyright 2004 American College of Cardiology Foundation.

Prophylactic temporary cardiac pacing has aroused debate for its role in a complicated anterior wall myocardial infarction. The left anterior descending artery is the major blood supply to the His bundle and the bundle branches, and an anterior wall infarction with new bundle branch block represents extensive myocardial damage and confers an increased risk of heart failure and mortality. Thrombolytic therapy or percutaneous coronary intervention takes precedence over placement of prophylactic cardiac pacing, because prophylactic pacing has not been shown to improve mortality. Transthoracic (transcutaneous) cardiac pacing is safe and usually effective [10], and would be a reasonable alternative to prophylactic transvenous cardiac pacing, particularly soon after the administration of thrombolytic therapy.

When right ventricular involvement complicates inferior myocardial infarction, cardiac output may be very sensitive to ventricular preload and AV synchrony. Therefore, AV sequential pacing is frequently the pacing modality of choice in patients with right ventricular infarction [11].
EQUIPMENT AVAILABLE FOR TEMPORARY PACING

Several methods of temporary pacing are currently available for use in the ICU. Transvenous pacing of the right ventricle or right atrium with a pacing catheter or modified pulmonary artery catheter is the most widely used technique; intraesophageal, transcutaneous, and epicardial pacing techniques are also available.

Transvenous Pacing Catheters

Some of the many transvenous pacing catheters available for use in the critical care setting are illustrated in Figure 18.1. Pacing catheters range in size from 4 Fr (1.2 mm) to 7 Fr (2.1 mm). In urgent situations, or where fluoroscopy is unavailable, a flow-directed flexible balloon-tipped catheter (Fig. 18.1, top) may be placed in the right ventricle using ECG guidance. After gaining access to the central venous circulation (Chapter 6), the catheter is passed into the vein and the balloon inflated. After advancing the catheter into the right ventricle, the balloon can be deflated and the catheter tip advanced to the right ventricular apex. Cardiac ultrasound can confirm placement of the catheter in the right ventricle [12]. Although the balloon-tipped catheter may avoid the need for fluoroscopy, placement may be ineffective in the setting of low blood flow during cardiac arrest or in the presence of severe tricuspid regurgitation. Stiff catheters (Fig. 18.1, middle) are easier to manipulate but require insertion under fluoroscopic or ultrasound guidance [13].
A flexible J-shaped catheter (Fig. 18.1, bottom), designed for temporary atrial pacing, is also available [14]. This lead is positioned by “hooking” it in the right atrial appendage under fluoroscopic guidance, providing stable contact with the atrial endocardium.

A multilumen pulmonary artery catheter is available with a right ventricular port. Placement of a small (2.4 Fr) bipolar pacing lead through the right ventricular lumen allows intracardiac pressure monitoring and pacing through a single catheter [15]. Details on its use and insertion are described in Chapter 19.

Utility of Ultrasonography for Transvenous Pacemaker Insertion

Ultrasonography has useful applications related to transvenous pacemaker insertion.

Real-time guidance of pacemaker insertion with ultrasonography is a safe, effective, and fast way to perform the procedure. It has advantage over fluoroscopic guidance, because it requires no patient transport or complex equipment and can be performed at the bedside of the critically patient. Ultrasonography guided insertion is performed more rapidly and with fewer complications than with fluoroscopic control [13,16].

The right atrium (RA), tricuspid valve (TV), and right ventricle (RV)
are imaged from the subcostal views or the right ventricular inflow view according to operator preference. If a femoral approach is used, the longitudinal view of inferior vena cava permits visualization of the pacer wire (Chapter 18 Video 18.1). The catheter tip is visualized as it enters the RA. The operator manipulates the catheter under direct visualization through the TV. Once in the RV cavity, the balloon is deflated and the catheter advanced into the RV apex. Visualization of the catheter approach to the RV apex requires an apical four-chamber view. Because it may be difficult to image the wire during its final advance into the RV apex, the procedure is done with ECG monitoring from catheter tip, so as to confirm final position with detection of a current of injury pattern. In intubated patients with inadequate image quality from transthoracic images, transesophageal echocardiography is an effective alternative. In this case, the bicaval view allows initial visualization of the catheter, whereas the mid-esophageal four-chamber view permits assessment of catheter movement into the RV.

**Esophageal Electrode**

An esophageal “pill” electrode allows atrial pacing and recording of atrial depolarizations without requiring central venous cannulation. Because the electrode can be uncomfortable and may not give consistent, stable capture, the esophageal electrode is typically limited to short-term use for diagnosis of arrhythmias in pediatric patients.

**Transcutaneous External Pacemakers**

Transcutaneous external pacemakers have external patch electrodes that deliver a higher current (up to 200 mA) and longer pulse duration (20 to 40 ms) than transvenous pacemakers. External pacing can be implemented immediately and the risks of central venous access avoided. Some patients may require sedation for the discomfort of skeletal muscle stimulation. Transcutaneous external pacemakers have been used to treat bradyasystolic cardiac arrest, symptomatic bradyarrhythmias, and overdrive pacing of tachyarrhythmias and prophylactically for conduction abnormalities during myocardial infarction. They may be particularly useful when transvenous pacing is unavailable, as in the prehospital setting, or relatively contraindicated, as during thrombolytic therapy for acute myocardial infarction [17]. When continued pacing is needed, transvenous pacing is preferable.
**Epicardial Pacing**

The placement of epicardial electrodes requires open thoracotomy. These electrodes are routinely placed electively during cardiac surgical procedures for use during the postoperative period. Typically, both atrial and ventricular electrodes are placed for use in diagnosis of postoperative atrial arrhythmias and for AV pacing. Because ventricular capture is not always reliable, in patients with underlying asystole or an unstable escape rhythm additional prophylactic transvenous pacing should be considered.

**Pulse Generators for Temporary Pacing**

Temporary pulse generators are capable of ventricular, atrial, and dual chamber sequential pacing with adjustable ventricular and atrial parameters that include pacing modes (synchronous or asynchronous), rates, current outputs (mA), sensing thresholds (mV), and AV pacing interval/delay (ms). Because these generators have atrial sensing/inhibiting capability, they are also set with an upper rate limit (to avoid rapid ventricular pacing while “tracking” an atrial tachycardia); in addition, an atrial pacing refractory period may be programmed (to avoid pacemaker-mediated/endless loop tachyarrhythmias).
CHOICE OF PACING MODE

A pacing mode must be selected when temporary cardiac pacing is initiated. Common modes for cardiac pacing are outlined in Table 18.3. The mode most likely to provide the greatest hemodynamic benefit should be selected. In patients with hemodynamic instability, establishing ventricular pacing is of paramount importance prior to attempts at AV sequential pacing.

### TABLE 18.3 Common Pacemaker Modes for Temporary Cardiac Pacing

<td>Dual-chamber pacing and sensing: atrial and ventricular pacing is on demand to provide a minimum rate, ventricular pacing follows a programmed A-V delay, and upper-rate pacing limit should be programmed</td>
</tr>
</tbody>
</table>

Ventricular pacing effectively counteracts bradycardia and is most frequently used in ICU patients; however, it cannot restore normal
cardiac hemodynamics because it disrupts AV synchrony [18,19]. In patients with noncompliant ventricles (ischemic heart disease, left ventricular hypertrophy, aortic stenosis, and right ventricular infarction), loss of the atrial contribution to ventricular stroke volume (the atrial “kick”) during ventricular pacing may result in increased atrial pressure; and intermittent mitral and tricuspid regurgitation with reduced cardiac output and blood pressure.

In addition to the hemodynamic benefit of atrial or AV sequential pacing, temporary atrial pacing after CABG has been shown to decrease the incidence of postoperative atrial fibrillation [20].
PROCEDURE TO ESTABLISH TEMPORARY PACING

After achieving venous access, most often via the internal jugular or subclavian approach (Chapter 6), the pacing catheter is advanced to the central venous circulation and then positioned in the right heart using fluoroscopic or ECG guidance [21]. To position the electrode using ECG guidance, the patient is connected to the limb leads of the ECG machine, and the distal (negative) electrode of the balloon-tipped pacing catheter is connected to lead V₁ with an alligator clip or a special adaptor supplied with the lead. Lead V₁ is then used to continuously monitor a unipolar intracardiac electrogram. The morphology of the recorded electrogram indicates the position of the catheter tip (Fig. 18.2). The balloon is inflated in the superior vena cava, and the catheter is advanced while observing the recorded intracardiac electrogram. When the tip of the catheter reaches the right ventricle, the balloon is deflated and the catheter advanced to the right ventricular apex. ST segment elevation of the intracardiac electrogram owing to a current of injury indicates contact of the catheter tip with the ventricular endocardium.
After the tip of the pacing catheter is satisfactorily inserted in the right ventricular apex, the leads are connected to the ventricular output connectors of the pulse generator, with the pacemaker box in the off position. The pacemaker is then set to asynchronous mode (VOO) and the ventricular rate set to exceed the patient’s intrinsic ventricular rate by 10 to 20 beats per minute. The threshold current for ventricular pacing is set at 5 to 10 mA. Then the pacemaker is switched on. Satisfactory ventricular pacing is evidenced by a wide QRS complex, with ST segment depression and T wave inversion immediately preceded by a pacemaker depolarization (spike). With pacing from the apex of the right ventricle, the paced rhythm usually demonstrates a pattern of left bundle branch block on the surface ECG [22].

Ventricular pacing is maintained as the output current for ventricular pacing is slowly reduced. The pacing threshold is defined as the lowest current at which consistent ventricular capture occurs. With the
ventricular electrode appropriately positioned at or near the apex of the right ventricle, a pacing threshold of less than 0.5 to 1.0 mA should be achieved. If the output current for continuous ventricular pacing is consistently greater than 1 to 1.5 mA, the pacing threshold is too high. Possible causes of a high pacing threshold include relatively refractory endomyocardial tissue (fibrosis) or, most commonly, unsatisfactory positioning of the pacing electrode. The tip of the pacing electrode should be repositioned in the region of the ventricular apex until satisfactory ventricular capture at a current of less than 1.0 mA is consistently maintained. The ventricular output is set to exceed the threshold current at least threefold to guarantee uninterrupted ventricular capture despite any modest increase in the pacing threshold.

The pacemaker is now in VOO mode. However, the pacing generator generally should be set in the VVI (“demand”) mode, because this prevents pacemaker discharge soon after any spontaneous activity in the paced chamber, while the heart lies in the electrically vulnerable period for induction of sustained ventricular arrhythmias. To set the pacemaker in VVI mode, the pacing rate is set at 10 beats per minute less than the intrinsic rate, and the sensitivity control is moved from asynchronous to the minimum sensitivity level. The sensitivity is gradually increased until pacing spikes appear. This level is the sensing threshold. The sensitivity is then set at a level slightly below the determined threshold and the pacing rate reset to the minimum desired ventricular rate.

If AV sequential pacing is desired, the atrial J-shaped pacing catheter should be advanced into the right atrium and rotated anteromedially to achieve a stable position in the right atrial appendage; however, positioning the atrial catheter usually requires fluoroscopy [23]. The leads are then connected to the atrial output of the pulse generator. The atrial current is set to 20 mA and the atrial pacing rate adjusted to at least 10 beats per minute greater than the intrinsic atrial rate. The AV interval is adjusted at 100 to 200 ms (shorter intervals usually provide better hemodynamics), and the surface ECG is inspected for evidence of atrial pacing (electrode depolarization and capture of the atrium at the pacing rate).

Atrial capture on ECG is indicated by atrial depolarization (P waves) immediately following the atrial pacing spikes. In patients with intact AV conduction, satisfactory atrial capture can be verified by shutting off the ventricular portion of the pacemaker and demonstrating AV synchrony during atrial pacing. As long as the atrial pacing rate continually exceeds the intrinsic sinus rate, the atrial P wave activity should track with the atrial pacing spike.

The DDD mode is the most commonly used setting in patients with atrial and ventricular leads. Although there is a risk of tracking atrial tachyarrhythmias in DDD mode, this risk can be mitigated by setting a
maximum tracking rate or an upper rate limit on the temporary pulse generator [24].
COMPLICATIONS OF TEMPORARY PACING

Transvenous pacing in the ICU setting is most often performed via the internal jugular or subclavian approach. Appropriate selection of the optimal route requires an understanding of the results and complications of each technique.

Complications of temporary pacing from any venous access route include pericardial friction rub, arrhythmia, right ventricular perforation, cardiac tamponade, infection, unintentional arterial injury, diaphragmatic stimulation, phlebitis, and pneumothorax. The Mayo Clinic experience revealed that percutaneous cannulation of the right internal jugular vein provided the simplest, most direct route to the right-sided cardiac chambers [25].

Complications of internal jugular venous cannulation may include pneumothorax, carotid arterial injury, venous thrombosis, and pulmonary embolism (Chapter 6) [26]. These risks are minimized by use of ultrasound, knowledge of anatomic landmarks, adherence to proved techniques, and use of a small-caliber needle to localize the vein before insertion of the large-caliber needle (for a full discussion, see Chapter 6). Full-dose systemic anticoagulation, thrombolytic therapy, and prior neck surgical procedures are relative contraindications to routine internal jugular vein cannulation.

Percutaneous subclavian venipuncture is also frequently used for insertion of temporary pacemakers [27]. This approach should be avoided in patients with severe obstructive lung disease or a bleeding diathesis (including thrombolytic therapy), in whom the risk of pneumothorax or bleeding is increased.

The femoral venous approach is used for electrophysiologic studies or during cardiac catheterization when the catheter is left in place for only a few hours. This approach is less desirable when long-term cardiac pacing is required, because there is a risk of deep venous thrombosis or infection. Central venous access by the subclavian or internal jugular route provides more stable long-term positioning of the pacing lead.
REFERENCES

Since their introduction into clinical practice in 1970 by Swan et al. [1], balloon-tipped, flow-directed pulmonary artery (PA) catheters (PACs) have found widespread use in the clinical management of critically ill patients. However, in recent years, both the safety and efficacy of these catheters have been brought into question. In this chapter, I review the physiologic basis for their use; some history regarding their development and use; the concerns raised about their use; and suggestions for appropriate use of the catheters and the information obtained from them.

**PHYSIOLOGIC RATIONALE FOR USE OF PULMONARY ARTERY CATHETER**

In unstable situations, during which hemodynamic changes often occur rapidly, clinical evaluation may be misleading. PACs allow for direct and indirect measurement of several major determinants and consequences of cardiac performance—preload, afterload, cardiac output (CO)—thereby supplying additional data to aid in clinical decision-making [2].

Cardiac function depends on the relationship between muscle length (preload); the load on the muscle (afterload); and the intrinsic property of contractility. Until the development of the flow-directed PA catheter, there was no way to assess all of these by using one instrument in a clinically useful way at bedside. The catheter allows the reflection of right ventricular (RV) preload (right atrial pressure); RV afterload (PA pressure); left ventricular preload—PA occlusion pressure (PAOP) or pulmonary capillary wedge pressure (PCWP)—and contractility (stroke volume or CO). Left ventricular afterload is reflected by the systemic arterial pressure. This information allows for the calculation of numerous parameters, including vascular resistances. However, monitors such as transthoracic or transesophageal echocardiography; esophageal Doppler;
bioreactance; and pulse contour analysis have become increasingly popular, thereby diminishing the use of the PAC.
CONTROVERSIES REGARDING USE OF PULMONARY ARTERY CATHETER

Despite all of the advantages of the PA catheter, a number of clinical studies have been published in the past 20 years that have shown either no benefit or an increased risk of morbidity or mortality associated with its use (See Table 19.1 for a summary of the evidence for its utility.) Consequently, a number of clinicians have elected to minimize the use of this monitoring device.

ARDS, acute respiratory distress syndrome; ICU, intensive care unit; ISS, injury security score; LOS, length of stay; PA, pulmonary artery; PAC, pulmonary artery catheter; RCT, randomized control trial.

Furthermore, the relationship of central venous (CV) pressure and PAOP to predict ventricular filling was studied in normal volunteers by Kumar et al. [43] who found that there was a poor correlation between initial CV pressure and PAOP, with both respective end diastolic ventricular volume and stroke volume indices. Their data call into question the basic tenet of the theoretical benefit of the PA catheter.
INDICATIONS FOR USE OF PULMONARY ARTERY CATHETER

Clinicians who use a PAC for monitoring should understand the fundamentals of the insertion technique; the equipment used; and the data that can be generated.

The use of PAC for monitoring has four central objectives: (a) to assess left or right ventricular function, or both; (b) to monitor changes in hemodynamic status; (c) to guide treatment with pharmacologic and nonpharmacologic agents; and (d) to provide prognostic information. The conditions under which PA catheterization may be useful are characterized by a clinically unclear or rapidly changing hemodynamic status. Table 19.2 is a partial listing of the indications. The use of PACs in specific disease entities is discussed in other chapters.

**TABLE 19.2 General Indications for Pulmonary Artery Catheterization**

- Management of complicated myocardial infarction
- Hypovolemia versus cardiogenic shock
- Ventricular septal rupture versus acute mitral regurgitation
- Severe left ventricular failure
- Right ventricular infarction
- Unstable angina
- Refractory ventricular tachycardia
- Assessment of respiratory distress
  - Cardiogenic versus noncardiogenic (e.g., acute respiratory distress syndrome) pulmonary edema
  - Primary versus secondary pulmonary hypertension
- Assessment of shock
  - Cardiogenic
  - Hypovolemic
  - Septic
  - Pulmonary embolism
- Assessment of therapy in selected individuals
Afterload reduction in patients with severe left ventricular function
Inotropic agent
Vasopressors
Beta-blockers
Temporary pacing (ventricular vs. atrioventricular)
Intra-aortic balloon counterpulsation
Mechanical ventilation (e.g., with positive end-expiratory pressure)
Management of postoperative open-heart surgical patients
Assessment of cardiac tamponade/constriction
Assessment of valvular heart disease
Perioperative monitoring of patients with unstable cardiac status during noncardiac surgery
Assessment of fluid requirements in critically ill patients
  Gastrointestinal hemorrhage
  Sepsis
  Acute renal failure
  Burns
  Decompensated cirrhosis
  Advanced peritonitis
Management of severe preeclampsia
CATHETER FEATURES AND CONSTRUCTION

The catheter is constructed from polyvinylchloride and has a pliable shaft that softens further at body temperature. Because polyvinylchloride has a high thrombogenicity, the catheters are generally coated with heparin. Heparin bonding of catheters, introduced in 1981, has been shown to be effective in reducing catheter thrombogenicity [44] but can cause heparin-induced thrombocytopenia (HIT). The standard catheter length is 110 cm, and the most commonly used external diameter is 5 or 7 French (Fr) (1 Fr = 0.0335 mm). A balloon is fastened 1 to 2 mm from the tip (Fig. 19.1); when inflated, it guides the catheter (by virtue of fluid dynamic drag) from the greater intrathoracic veins through the right heart chambers into the PA. When fully inflated in a vessel of sufficiently large caliber, the balloon protrudes above the catheter tip, thus distributing tip forces over a large area and minimizing the chances for endocardial damage or arrhythmia induction during catheter insertion (Fig. 19.2). Progression of the catheter is stopped when it impacts in a PA slightly smaller in diameter than the fully inflated balloon. From this position, the PAOP is obtained. Balloon capacity varies according to catheter size, and the operator must be aware of the individual balloon’s maximal inflation volume, as recommended by the manufacturer. The balloon is usually inflated with air, but filtered carbon dioxide should be used in any situation in which balloon rupture might result in access of the inflation medium to the arterial system (e.g., if a right-to-left intracardiac shunt or a pulmonary arteriovenous fistula is suspected). If carbon dioxide is used, periodic deflation and reinflation may be necessary, because carbon dioxide diffuses through the latex balloon at a rate of approximately 0.5 cm$^3$ per
A variety of catheter constructions are available, each designed for particular clinical applications. Double-lumen catheters allow balloon inflation through one lumen, and a distal opening at the tip of the catheter is used to measure intravascular pressures and sample blood. Triple-lumen catheters have a proximal port terminating 30 cm from the tip of the catheter, allowing simultaneous measurement of right atrial and PA or occlusion pressures. The most commonly used PAC in the ICU setting is a quadruple-lumen catheter, which has a lumen containing electrical leads for a thermistor positioned at the catheter surface 4 cm proximal to its tip (Fig. 19.1) [45]. The thermistor measures PA blood temperature and allows for thermodilution CO measurements. A five-lumen catheter is also available, with the fifth lumen opening 40 cm from the tip of the catheter. The fifth lumen provides additional central venous access for fluid or medication infusions when peripheral access is limited or when drugs requiring infusion into a large vein (e.g., dopamine and epinephrine) are used. Figure 19.2 shows the balloon on the tip inflated.
Several special-purpose PAC designs are available. Pacing PACs incorporate two groups of electrodes on the catheter surface, enabling intracardiac electrocardiographic (ECG) recording or temporary cardiac pacing [46]. These catheters are used for emergency cardiac pacing, although it is often difficult to position the catheter for reliable simultaneous cardiac pacing and PA pressure measurements. A five-lumen catheter allows passage of a specially designed 2.4-Fr bipolar pacing electrode (probe) through the additional lumen (located 19 cm from the catheter tip) and allows emergency temporary intracardiac pacing without the need for a separate central venous puncture. The pacing probe is Teflon coated to allow easy introduction through the pacemaker port lumen; the intracavitary part of the probe is heparin impregnated to reduce the risk of thrombus formation. One report demonstrated satisfactory ventricular pacing in 19 of 23 patients using this catheter design (83% success rate) [47]. When a pacing probe is not in use, the fifth lumen may be used for additional central venous access or continuous RV pressure monitoring.

Continuous mixed venous oxygen saturation measurement is clinically available using a fiber-optic five-lumen PAC [48]. Catheters equipped with a fast-response (95 ms) thermistor and intracardiac ECG-monitoring electrodes are also available. These catheters allow for determination of the RV ejection fraction and RV systolic time intervals in critically ill patients [49]. Aside from the intermittent determination of CO by bolus administration of cold injectate, PACs have been adapted to determine near continuous CO by thermal pulses generated by a heating
filament on the catheter to produce temperature changes [50]. The accuracy and reliability of CO determination by this heating–cooling cycle have been confirmed [51].

Pressure Transducers

Hemodynamic monitoring requires a system able to convert changes in intravascular pressure into electrical signals suitable for interpretation. The most commonly used hemodynamic monitoring system is a catheter–tubing–transducer system. A fluid-filled intravascular catheter is connected to a transducer by a fluid-filled tubing system (For more details, see the discussion in Chapters 7 and 28.)
GENERAL CONSIDERATIONS

Recommendations of manufacturers should be carefully followed. All catheter manufacturers have detailed insertion and training materials.

PA catheterization can be performed in any hospital location where continuous ECG and hemodynamic monitoring are possible and where equipment and supplies needed for cardiopulmonary resuscitation are readily available. Fluoroscopy is not essential, but it can facilitate difficult placements. Properly constructed beds and protective aprons are mandatory for safe use of fluoroscopic equipment. Meticulous attention to sterile technique is of obvious importance; all involved personnel must wear sterile caps, gowns, masks, and gloves, and the patient must be fully covered by sterile drapes.

The catheter should be inserted percutaneously (not by cutdown) into the basilic, brachial, femoral, subclavian, or internal jugular veins by using techniques described in Chapter 6. Threading the catheter into the PA is more difficult from the basilic, brachial, or femoral vein.

Typical Catheter Insertion Procedure

The procedures for typical catheter insertion are as follows:

1. Prepare and connect pressure tubing, manifolds, stopcocks, and transducers. Remove the sterile balloon-tipped catheter from its container. Balloon integrity may be tested by submerging the balloon in a small amount of fluid and checking for air leaks as the balloon is inflated (using the amount of air recommended by the manufacturer). Deflate the balloon.

2. After a time out, insert a central venous cannula or needle into the vein as described in Chapter 6. Using the Seldinger technique, thread the guidewire contained in the catheter kit into the vein and remove the catheter or needle (Figs. 19.3 and 19.4).
3. Make a small incision with a scalpel to enlarge the puncture site (Fig. 19.5). While holding the guidewire stationary, thread a vessel dilator-sheath apparatus (the size should be 8 Fr if a 7-Fr catheter is to be used) over the guidewire and advance it into the vessel, using a twisting motion to get through the puncture site (Fig. 19.6). The dilator and sheath should only be advanced until the tip of the sheath is in the vessel—estimated by the original depth of the cannula or needle required to access the vein. At that point, the dilator and guidewire are held stationary and the sheath is advanced off the dilator into the vessel. Advancing the dilator further may cause great vessel or cardiac damage.

4. Remove the guidewire and vessel dilator, leaving the introducer sheath in the vessel (Fig. 19.7). Suture the sheath in place.

5. Pass the proximal portion of the catheter to an assistant and have that person attach the stopcock-pressure tubing-transducer system to the right atrial and PA ports of the PA catheter. Flush the proximal and distal catheter lumens with normal saline.

6. If a sterile sleeve adapter is to be used, insert the catheter through it and pull the adapter proximally over the catheter to keep it out of the way. Once the catheter is advanced to its desired intravascular location, attach the distal end of the sleeve adapter to the introducer sheath hub.

7. Pass the catheter through the introducer sheath into the vein (Fig. 19.8). Advance it, using the marks on the catheter shaft indicating 10-cm distances from the tip, until the tip is in the right atrium. This requires advancement of approximately 35 to 40 cm from the left antecubital fossa, 10 to 15 cm from the internal jugular vein, 10 cm from the subclavian vein, and 35 to 40 cm from the femoral vein. A right atrial waveform on the monitor, with appropriate fluctuations accompanying respiratory changes or cough, confirms proper intrathoracic location (Fig. 19.9, center). If desired, obtain right atrial blood for oxygen saturation from the distal port. Flush the distal lumen with saline and record the right atrial pressures. (Occasionally, it is necessary to inflate the balloon to keep the tip from adhering to the atrial wall during blood aspiration.)

8. With the catheter tip in the right atrium, inflate the balloon with the recommended amount of air or carbon dioxide (Fig. 19.9A). Inflation of the balloon should be associated with a slight feeling of resistance—if it is not, suspect balloon rupture and do not attempt further inflation or advancement of the catheter before properly reevaluating balloon integrity. If significant resistance to balloon inflation is encountered, suspect malposition of the catheter in a small vessel; withdraw the
catheter and readvance it to a new position. Do not use liquids to inflate the balloon, because they might be irretrievable and could prevent balloon deflation.

9. With the balloon inflated, advance the catheter until an RV pressure tracing is seen on the monitor (Fig. 19.9, center). Obtain and record RV pressures. Catheter passage into and through the RV is an especially risky time in terms of arrhythmias. Maintaining balloon inflation in the RV minimizes ventricular irritation (Fig. 19.9B), but it is important to monitor vital signs and ECG throughout the entire insertion procedure. Elevating the head of the bed to 5 degrees and a right tilt position will facilitate the passage of the catheter through the right ventricle and minimize the generation of arrhythmias.

10. Continue advancing the catheter until the diastolic pressure tracing rises above that in the RV (Fig. 19.9, center), indicating PA placement (Fig. 19.9C). If an RV trace still appears after the catheter has been advanced 15 cm beyond the original distance needed to reach the right atrium, suspect curling in the ventricle; deflate the balloon, withdraw it to the right atrium, then reinflate it and try again. Advancement beyond the PA position results in a fall on the pressure tracing from the levels of systolic pressure noted in the RV and PA. When this is noted, record the PAOP (Fig. 19.9, center, D) and deflate the balloon. Phasic PA pressure should reappear on the pressure tracing when the balloon is deflated. If it does not, pull back the catheter with the deflated balloon until the PA tracing appears. With the balloon deflated, blood may be aspirated for oxygen saturation measurement. Watch for intermittent RV tracings indicating slippage of the catheter backward into the ventricle.

11. Carefully record the balloon inflation volume needed to change the PA pressure tracing to the PAOP tracing. If PAOP is recorded with an inflation volume significantly lower than the manufacturer’s recommended volume, or if subsequent PAOP determinations require decreasing amounts of balloon inflation volume as compared with an initial appropriate amount, the catheter tip has migrated too far peripherally and should be pulled back immediately.

12. Secure the catheter in the correct PA position by suturing or taping it to the skin to prevent unintentional advancement. Apply a chlorhexidine-impregnated transparent dressing at the introducer insertion site.

13. Order a chest radiograph to confirm catheter position; the catheter tip should appear no more than 3 to 5 cm from the midline. To assess whether peripheral catheter migration has occurred, daily chest radiographs are recommended to supplement pressure monitoring.
and checks on balloon inflation volumes. An initial cross-table lateral radiograph may be obtained in patients on positive end-expiratory pressure (PEEP) to rule out superior catheter placement.

**FIGURE 19.3** A: Easy blood aspiration has been demonstrated using the guidewire introducer needle. B: The inner needle is removed. C: The spring guidewire is advanced, soft end first, through the cannula into the vessel. D: With the guidewire held in place, the cannula is withdrawn from the vessel by being pulled over and off the length of the guidewire.

FIGURE 19.7 The guidewire and vessel dilator are removed, leaving the introducer sheath in the vessel.
FIGURE 19.8 The catheter is passed through the introducer sheath into the vein.
**FIGURE 19.9** A: With the catheter tip in the right atrium, the balloon is inflated. B: The catheter is advanced into the right ventricle with the balloon inflated, and right ventricle pressure tracings are obtained. (Center): Waveform tracings generated as the balloon-tipped catheter is advanced through the right heart chambers into the pulmonary artery. (Adapted from Wiedmann HP, Matthey MA, Matthey RA: Cardiovascular pulmonary monitoring in the intensive care unit (Part 1) Chest 85:537;1984, with permission.) C: The catheter is advanced through the pulmonary valve into the pulmonary artery. A rise in diastolic pressure should be noted. D: The catheter is advanced to the pulmonary artery occlusion pressure position. A typical pulmonary artery occlusion pressure tracing should be noted with a and v waves. E: The balloon is deflated. Phasic pulmonary artery pressure should reappear on the monitor. (See text for details.)

**Special Considerations**

In certain disease states (right atrial or RV dilatation, severe pulmonary hypertension, severe tricuspid insufficiency, low CO syndromes), it may be difficult to position a flow-directed catheter properly. These settings
may require fluoroscopic guidance to aid in catheter positioning. Infusion of 5 to 10 mL of cold saline through the distal lumen may stiffen the catheter and aid in positioning. Alternatively, a 0.025-cm guidewire 145 cm long may be used to stiffen the catheter when placed through the distal lumen of a 7-Fr PA catheter. This manipulation should be performed only under fluoroscopic guidance by an experienced operator. Rarely, nonflow-directed PACs (e.g., Courand catheters) may be required. Because of their rigidity, these catheters have the potential to perforate the right heart and must be placed only under fluoroscopy by a physician experienced in cardiac catheterization techniques.

Utility of Ultrasonography for Pulmonary Artery Catheter Insertion

Ultrasonography has useful application related to PAC insertion. The PAC is usually inserted without difficulty using standard flow guided flotation technique in conjunction with real-time observation of the typical waveforms. Occasionally, the insertion may be difficult, particularly in patients with high right sided pressures, dilated right heart chambers, and/or severe tricuspid regurgitation. Real time guidance of PAC insertion with ultrasonography is a safe, effective, and fast method of insertion that has advantage over fluoroscopic guidance, given that it can be performed at the bedside of the critically patient and it requires no patient transport or complex equipment [52,53].

The right atrium (RA), tricuspid valve (TV), and right ventricle (RV) are imaged from the subcostal view or the right ventricular inflow view according to operator preference (See Chapter 18 Video 18.1 for an example of device insertion). The catheter tip is visualized as it enters the RA. The operator manipulates the catheter under direct visualization through the RV. The catheter is visualized as it enters the main PA from the short axis view of the base of the heart. Alternatively, it is visualized from the subcostal PA view where, imaging conditions permitting; it may be seen entering the right or left PA. In patients with inadequate image quality for transthoracic images, transesophageal echocardiography is an effective alternative [54] (Chapter 19 Video 19.1). In this case, the bicaval view allows initial visualization of the catheter, the mid-esophageal four chamber view permits assessment of catheter movement into the RV, the and final placement is visualized from the upper esophageal PA view.
Measurement of a variety of hemodynamic parameters and oxygen saturations is possible using the PAC. A summary of normal values for these parameters is found in Tables 19.3 and 19.4.

Pressures

Right Atrium

With the tip of the PAC in the right atrium (Fig. 19.9A), the balloon is deflated and a right atrial waveform recorded (Fig. 19.10). Normal resting right atrial pressure is 0 to 6 mm Hg. Two major positive atrial pressure waves, the a wave and v wave, can usually be recorded. On occasion, a third positive wave, the c wave, can also be seen. The a wave is caused by atrial contraction and follows the simultaneously recorded ECG P wave [55]. The a wave peak generally follows the peak of the electrical P wave by approximately 80 ms. The v wave represents the pressure generated by venous filling of the right atrium while the tricuspid valve is closed. The peak of the v wave occurs at the end of ventricular systole when the atrium is maximally filled, corresponding to the point near the end of the T wave on the ECG. The c wave is caused by the sudden motion of the atrioventricular valve ring toward the right atrium at the onset of ventricular systole. The c wave follows the a wave by a time equal to the ECG P–R interval. The c wave is more readily visible in cases of P–R prolongation. The x descent follows the c wave and reflects atrial relaxation. The y descent is caused by rapid emptying of the atrium after opening of the tricuspid valve. The mean right atrial pressure decreases during inspiration with spontaneous respiration (secondary to a decrease in intrathoracic pressure), whereas the a and v waves and the x and y descents become more prominent. Once a multilumen PAC is in position, right atrial blood can be sampled and pressure monitored using the proximal lumen. It should be noted that the pressures obtained via the proximal lumen may not accurately reflect right atrial pressure owing to positioning of the lumen against the atrial wall or within the introducer.
sheath.

**FIGURE 19.10** Stylized representation of a right atrial waveform in relation to heart sounds. (See text for discussion of a, c, and v waves and x and y descents.) S₁, first heart sound; S₂, second heart sound.

**Right Ventricle**

The normal resting RV pressure is 17 to 30/0 to 6 mm Hg, recorded when the PAC crosses the tricuspid valve (Fig. 19.9B). The RV systolic pressure should equal the PA systolic pressure (except in cases of pulmonic stenosis or RV outflow tract obstruction). The RV diastolic pressure should equal the mean right atrial pressure during diastole when the tricuspid valve is open. Introduction of the catheter with a pacing lumen allows continuous monitoring of RV hemodynamics when the pacing wire is not in place. Using special catheters, RV end-diastolic volume index and RV ejection fraction can be accurately measured [56].

**Pulmonary Artery**

With the catheter in proper position and the balloon deflated, the distal lumen transmits PA pressure (Fig. 19.9E). Normal resting PA pressure is 15 to 30/5 to 13 mm Hg, with a mean pressure of 10 to 18 mm Hg. The PA waveform is characterized by a systolic peak and diastolic trough with a dicrotic notch due to closure of the pulmonic valve. The peak PA systolic pressure occurs in the T wave of a simultaneously recorded ECG.

Because the pulmonary vasculature is normally a low-resistance circuit, PA diastolic pressure (PADP) is closely related to mean PAOP (PADP is usually 1 to 3 mm Hg higher than mean PAOP) and thus can be used as an index of left ventricle filling pressure in patients in whom an occlusion pressure is unobtainable or in whom PADP and PAOP have been shown to correlate closely. However, if pulmonary vascular resistance is increased, as in pulmonary embolic disease, pulmonary fibrosis, or reactive pulmonary hypertension (see Chapter 174), PADP may markedly
Pulmonary Artery Occlusion Pressure

An important application of the balloon flotation catheter is the recording of PAOP. This measurement is obtained when the inflated balloon impacts a slightly smaller branch of the PA (Fig. 19.9D). In this position, the balloon stops the flow, and the catheter tip senses pressure transmitted backward through the static column of blood from the next active circulatory bed—the pulmonary veins. Pulmonary venous pressure is a prime determinant of pulmonary congestion and thus of the tendency for fluid to shift from the pulmonary capillaries into the interstitial tissue and alveoli. Also, pulmonary venous pressure and PAOP closely reflect left atrial pressure (except in rare instances, such as pulmonary veno-occlusive disease, in which there is obstruction in the small pulmonary veins), and serve as indices of left ventricular filling pressure [57]. The PAOP is required to assess left ventricular filling pressure, because multiple studies have demonstrated that right atrial (e.g., central venous) pressure correlates poorly with PAOP [58].

The PAOP is a phase-delayed, amplitude-dampened version of the left atrial pressure. The normal resting PAOP is 2 to 12 mm Hg and averages 2 to 7 mm Hg below the mean PA pressure. The PAOP waveform is similar to that of the right atrium, with a, c, and v waves and x and y descents (Fig. 19.10). However, in contradistinction to the right atrial waveform, the PAOP waveform demonstrates a v wave that is slightly larger than the a wave [13]. Because of the time required for left atrial mechanical events to be transmitted through the pulmonary vasculature, PAOP waveforms are further delayed when recorded with a simultaneous ECG. The peak of the a wave follows the peak of the ECG P wave by approximately 240 ms, and the peak of the v wave occurs after the ECG T wave has been inscribed. Occlusion position is confirmed by withdrawing a blood specimen from the distal lumen and measuring oxygen saturation. Measured oxygen saturation of 95% or more is satisfactory [57]. The lung segment from which the sample is obtained will be well ventilated if the patient breathes slowly and deeply.

A valid PAOP measurement requires a patent vascular channel between the left atrium and catheter tip. Thus, the PAOP approximates pulmonary venous pressure (and therefore left atrial pressure) only if the
catheter tip lies in Zone 3 of the lungs [55] (The lung is divided into three physiologic zones, dependent on the relationship of PA, pulmonary venous, and alveolar pressures. In Zone 3, the PA and pulmonary venous pressure exceed the alveolar pressure, ensuring an uninterrupted column of blood between the catheter tip and the pulmonary veins.). If, on portable lateral chest radiograph, the catheter tip is below the level of the left atrium (posterior position in supine patients), it can be assumed to be in Zone 3. This assumption holds if applied PEEP is less than 15 cm H₂O and the patient is not markedly volume depleted. Whether the catheter is positioned in Zone 3 may also be determined by certain physiologic characteristics (Table 19.5). A catheter occlusion outside Zone 3 shows marked respiratory variation, an unnaturally smooth vascular waveform, and misleading high pressures.

| TABLE 19.5 Checklist for Verifying Position of Pulmonary Artery Catheter |
|---------------------------------|-----------------|------------------|
| Zone 3                          | Zone 1 or 2     |
| PAOP contour                    | Cardiac ripple (A + V waves) | Unnaturally smooth |
| PAD versus PAOP                | PAD > PAOP      | PAD < PAOP       |
| PEEP trial                      | Δ PAOP <½ ΔPEEP | Δ PAOP >½ ΔPEEP  |
| Respiratory variation of PAOP   | < ½ P_{ALV}     | ≥ ½ Δ P_{ALV}    |
| Catheter-tip location           | LA level or below | Above LA level   |

With a few exceptions [59], estimates of capillary hydrostatic filtration pressure from PAOP are acceptable. It should be noted that measurement of PAOP does not take into account capillary permeability, serum colloid osmotic pressure, interstitial pressure, or actual pulmonary capillary resistance. These factors all play roles in the formation of pulmonary edema, and the PAOP should be interpreted in the context of the specific clinical situation.

Mean PAOP correlates well with left ventricular end-diastolic pressure (LVEDP), provided the patient has a normal mitral valve and normal left ventricular function. In myocardial infarction, conditions with decreased left ventricular compliance (e.g., ischemia and left ventricular hypertrophy), and conditions with markedly increased left ventricular
filling pressure (e.g., dilated cardiomyopathy), the contribution of atrial contraction to left ventricular filling is increased. Thus, the LVEDP may be significantly higher than the mean left atrial pressure or PAOP [55].

The position of the catheter can be misinterpreted in patients with the presence of giant v waves. The most common cause of these v waves is mitral regurgitation. During this condition, left ventricular blood floods a normal-sized, noncompliant left atrium during ventricular systole, causing giant v waves in the occlusion pressure tracing (Fig. 19.11). The giant v wave of mitral regurgitation may be transmitted to the PA tracing, yielding a bifid PA waveform composed of the PA systolic wave and the v wave. Because the catheter is occluded, the PA systolic wave is lost, but the v wave remains. It is important to note that the PA systolic wave occurs earlier in relation to the QRS complex of a simultaneously recorded ECG (between the QRS and T waves) than does the v wave (after the T wave).

Although a large v wave is not diagnostic of mitral regurgitation and is not always present in this circumstance, acute mitral regurgitation remains the most common cause of giant v waves in the PAOP tracing. Prominent v waves may occur whenever the left atrium is distended and noncompliant owing to left ventricular failure from any cause (e.g., ischemic heart disease and dilated cardiomyopathy) [60], or secondary to the increased pulmonary blood flow in acute ventricular septal defect. Acute mitral regurgitation is the rare instance when the PA end-diastolic pressure may be lower than the computer-measured mean occlusion pressure.
End expiration provides a readily identifiable reference point for PAOP interpretation because pleural pressure returns to baseline at the end of passive deflation (approximately equal to atmospheric pressure). Pleural pressure can exceed the normal resting value with active expiratory muscle contraction or use of PEEP. How much PEEP is transmitted to the pleural space cannot be estimated easily, because it varies depending on lung compliance and other factors. When normal lungs deflate passively, end-expiratory pleural pressure increases by approximately one half of the applied PEEP. In patients with reduced lung compliance (e.g., patients with acute respiratory distress syndrome; ARDS), the transmitted fraction may be one-fourth or less of the PEEP value. In the past, PEEP levels greater than 10 mm Hg were thought to interrupt the column of blood between the left atrium and PAC tip, causing the PAOP to reflect alveolar pressure more accurately than left atrial pressure. However, two studies suggest that this may not hold true in all cases. Teboul et al. [61] could find no significant discrepancy between PAOP and simultaneously measured LVEDP at PEEP levels of 0, 10, and 16 to 20 cm H₂O in patients with ARDS. He hypothesized that (a) a large intrapulmonary right-to-left shunt may provide a number of microvessels shielded from alveolar pressure, allowing free communication from PA to pulmonary veins, or (b) in ARDS, both vascular and lung compliance may decrease, reducing transmission of alveolar pressure to the pulmonary microvasculature and maintaining an uninterrupted blood column from the catheter tip to the left atrium.

Although it is difficult to estimate precisely the true transmural vascular pressure in a patient on PEEP, temporarily disconnecting PEEP to measure PAOP is not recommended. Because the hemodynamics have been destabilized, these measurements will be of questionable value. Venous return increases acutely after discontinuation of PEEP [61], and abrupt removal of PEEP will cause hypoxia, which may not reverse quickly on reinstitution of PEEP [62].

Cardiac Output

Thermodilution Technique

A catheter equipped with a thermistor 4 cm from its tip allows calculation of CO by using the thermodilution principle [45,63]. The thermodilution principle holds that if a known quantity of cold solution is introduced into the circulation and adequately mixed (passage through two valves and a
ventricle is adequate), the resultant cooling curve recorded at a
downstream site allows for calculation of net blood flow. CO is inversely
proportional to the integral of the time-versus-temperature curve.
In practice, a known amount of cold or room temperature solution
(typically 10 mL of 0.9% saline in adults, and 5 mL of 0.9% saline in
children) is injected into the right atrium via the catheter’s proximal port.
The thermistor allows recording of the baseline PA blood temperature
and subsequent temperature change. The resulting curve is usually
analyzed by computer, although it can be analyzed manually by simple
planimetric methods. Correction factors are added by catheter
manufacturers to account for the mixture of cold indicator with warm
residual fluid in the catheter injection lumen and the heat transfer from
the catheter walls to the cold indicator.
Reported coefficients of variation using triplicate determinations, using
10 mL of cold injectate and a bedside computer, are approximately 4% or
less. Variations in the rate of injection can also introduce error into CO
determinations, and it is thus important that the solution be injected as
rapidly as possible. Careful attention must be paid to the details of this
procedure; even then, changes of less than 10% to 15% above or below an
initial value may not truly establish directional validity. Thermodilution
CO is inaccurate in low-output states, tricuspid regurgitation, and in
cases of atrial or ventricular septal defects [64].
Normal values for arterial–venous oxygen content difference, mixed
venous oxygen saturation, and CO can be found in Table 19.6.

| TABLE 19.6 Selected Hemodynamic Variables Derived from Right Heart Catheterization |
|-----------------------------------------------|---------------------------------|
| **Hemodynamic variable**                      | **Normal range**                |
| Arterial–venous content difference            | 3.5–5.5 mL/100 mL               |
| Cardiac index                                 | 2.5–4.5 L/min/m²                |
| Cardiac output                                | 3.0–7.0 L/min                   |
| Left ventricular stroke work index            | 45–60 g/beat/m²                 |
| Mixed venous oxygen content                   | 18.0 mL/100 mL                  |
| Mixed venous saturation                       | 75% (approximately)             |
| Oxygen consumption                            | 200–250 mL/min                  |
| Pulmonary vascular resistance                 | 120–250 dynes/sec/cm²           |

### Analysis of Mixed Venous Blood

CO can be approximated merely by examining mixed venous (PA) oxygen saturation. Theoretically, if CO rises, then the mixed venous oxygen partial pressure will rise, because peripheral tissues need to exact less oxygen per unit of blood. Conversely, if CO falls, peripheral extraction from each unit will increase to meet the needs of metabolizing tissues. Serial determinations of mixed venous oxygen saturation may display trends in CO. Normal mixed venous oxygen saturation is 70% to 75%; values of less than 60% are associated with heart failure and values of less than 40% with shock [65]. Potential sources of error in this determination include extreme low-flow states where poor mixing may occur, contamination of desaturated mixed venous blood by saturated pulmonary capillary blood when the sample is aspirated too quickly through the nonwedged catheter or in certain disease states (e.g., sepsis) where microcirculatory shunting may occur. Fiber-optic reflectance oximetry PACs can continuously measure and record mixed venous oxygen saturations in appropriate clinical situations [48].

### Derived Parameters

Useful hemodynamic parameters that can be derived using data with PACs include the following:

1. Cardiac index = CO (L per minute)/BSA (m²)
2. Stroke volume = CO (L per minute)/heart rate (beats per minute)
3. Stroke index = CO (L per minute)/((heart rate [beats per minute] × BSA [m²])
1. Mean arterial pressure (mm Hg) = \([2 \times \text{diastolic}] + \text{systolic}/3\)

2. Systemic vascular resistance (dyne/s/cm\(^{-5}\)) = \(((\text{mean arterial pressure} - \text{mean right atrial pressure (mm Hg)}) \times 80)/\text{CO (L per minute)}\)

3. Pulmonary arteriolar resistance (dyne/s/cm\(^{-5}\)) = \(((\text{mean PA pressure} - \text{PAOP (mm Hg)}) \times 80)/\text{CO (L per minute)}\)

4. Total pulmonary resistance (dyne/s/cm\(^{-5}\)) = \(((\text{mean PA pressure (mm Hg)}) \times 80)/\text{CO (L per minute)}\)

5. Left ventricular stroke work index = 1.36 (mean arterial pressure – PAOP) \times \text{stroke index}/100

6. Oxygen delivery (DO\(_2\))(mL/min/m\(^2\)) = \text{cardiac index} \times \text{arterial O}_2 \text{ content} \times 10

Normal values are listed in Table 19.6.
CLINICAL APPLICATIONS OF THE PULMONARY ARTERY CATHETER

Normal Resting Hemodynamic Profile

The finding of normal CO associated with normal left and right heart filling pressures is useful in establishing a noncardiovascular basis to explain abnormal symptoms or signs and as a baseline to gauge a patient’s disease progression or response to therapy. Right atrial pressures of 0 to 6 mm Hg, PA systolic pressures of 15 to 30 mm Hg, PADPs of 5 to 12 mm Hg, PA mean pressures of 9 to 18 mm Hg, PAOP of 5 to 12 mm Hg, and a cardiac index exceeding 2.5 L/min/m² characterize a normal cardiovascular state at rest.

Table 19.7 summarizes specific hemodynamic patterns for a variety of disease entities in which PACs have been indicated and provide clinical information that can impact patient care.

Minor and major complications associated with bedside balloon flotation PA catheterization have been reported (Table 19.8). During the 1970s, in the first 10 years of clinical catheter use, a number of studies reported a relatively high incidence of certain complications. Consequent revision of guidelines for PAC use and improved insertion and maintenance techniques resulted in a decreased incidence of these complications in the 1980s [66]. The majority of complications are avoidable by scrupulous attention to detail in catheter placement and maintenance.

Complications Associated with Central Venous Access

The insertion techniques and complications of central venous cannulation are discussed in Chapter 6. Reported local vascular complications include local arterial or venous hematomas, unintentional entry of the catheter into the carotid system, atrioventricular fistulas, and pseudoaneurysm formation [67]. Adjacent structures, such as the thoracic duct, can be damaged, with resultant chylothorax formation. Pneumothorax can be a serious complication of insertion, although the incidence is relatively low (1% to 2%) [67]. The incidence of pneumothorax is higher with the subclavian approach than with the internal jugular approach in some reports [68], but other studies demonstrate no difference between the two sites [69]. The incidence of complications associated with catheter insertion is generally considered to be inversely proportional to the operator’s experience.
Balloon Rupture

Balloon rupture occurred more frequently in the early 1970s than it does now and was generally related to exceeding recommended inflation volumes. The main problems posed by balloon rupture are air emboli gaining access to the arterial circulation and balloon fragments embolizing to the distal pulmonary circulation. If rupture occurs during catheter insertion, the loss of the balloon’s protective cushioning function can predispose to endocardial damage and attendant thrombotic and arrhythmic complications.

Knotting

Knotting of a catheter around itself is most likely to occur when loops form in the cardiac chambers and the catheter is repeatedly withdrawn and readvanced [70]. Knotting is avoided if care is taken not to advance the catheter significantly beyond the distances at which entrance to the ventricle or PA would ordinarily be anticipated. Knotted catheters usually can be extricated transvenously; guidewire placement, venotomy, or more extensive surgical procedures are occasionally necessary.

Knotting of PACs around intracardiac structures [71] or other intravascular catheters has been reported. Rarely, entrapment of a PAC in cardiac sutures after open-heart surgery has been reported, requiring varying approaches for removal [72].

Pulmonary Infarction

Peripheral migration of the catheter tip (caused by catheter softening and loop tightening over time) with persistent, undetected wedging in small branches of the PA is the most common mechanism underlying pulmonary ischemic lesions attributable to PACs [73]. These lesions are usually small and asymptomatic, often diagnosed solely on the basis of changes in the chest radiograph that demonstrate an occlusion-shaped pleural-based density with a convex proximal contour.

Severe infarctions are usually produced if the balloon is left inflated in the occlusion position for an extended period, thus obstructing more central branches of the PA, or if solutions are injected at relatively high pressure through the catheter lumen in an attempt to restore an apparently damped pressure trace. Pulmonary embolic phenomena resulting from thrombus formation around the catheter or over areas of endothelial damage can also result in pulmonary infarction.
The reported incidence of pulmonary infarction secondary to PACs in 1974 was 7.2% [73], but subsequent studies reported much lower rates of pulmonary infarction. Boyd et al. [74] found a 1.3% incidence of pulmonary infarction in a prospective study of 528 PA catheterizations. Sise et al. [75] reported no pulmonary infarctions in a prospective study of 319 PAC insertions. Use of continuous saline flush solutions and careful monitoring of PA waveforms are important reasons for the decreased incidence of this complication.

Pulmonary Artery Perforation

A serious and feared complication of PA catheterization is rupture of the PA leading to hemorrhage, which can be massive and sometimes fatal [76,77]. Rupture may occur during insertion or may be delayed a number of days [77]. PA rupture or perforation has been reported in approximately 0.1% to 0.2% of patients [68,78]. Pathologic data suggest the true incidence of PA perforation is somewhat higher [79]. Proposed mechanisms by which PA rupture can occur include (a) an increased pressure gradient between PAOP and PA pressure brought about by balloon inflation and favoring distal catheter migration, where perforation is more likely to occur; (b) an occluded catheter tip position favoring eccentric or distended balloon inflation with a spearing of the tip laterally and through the vessel; (c) cardiac pulsation causing shearing forces and damage as the catheter tip repeatedly contacts the vessel wall; (d) presence of the catheter tip near a distal arterial bifurcation where the integrity of the vessel wall against which the balloon is inflated may be compromised; and (e) simple lateral pressure on vessel walls caused by balloon inflation (this tends to be greater if the catheter tip was occluded before inflation began). Patient risk factors for PA perforation include pulmonary hypertension, mitral valve disease, advanced age, hypothermia, and anticoagulant therapy. In patients with these risk factors and in whom PADP reflects PAOP reasonably well, avoidance of subsequent balloon inflation altogether constitutes prudent prophylaxis.

Another infrequent but life-threatening complication is false aneurysm formation associated with rupture or dissection of the PA [80]. Technique factors related to PA hemorrhage are distal placement or migration of the catheter; failure to remove large catheter loops placed in the cardiac chambers during insertion; excessive catheter manipulation; use of stiffer catheter designs; and multiple or prolonged balloon inflations. Adherence to strict technique may decrease the incidence of this complication. In a prospective study reported in 1986, no cases of PA rupture occurred in 1,400 patients undergoing PA catheterization for cardiac surgery [69].

PA perforation typically presents with massive hemoptysis. Emergency
management includes immediate occlusion arteriogram and bronchoscopy; intubation of the unaffected lung; and consideration of emergency lobectomy or pneumonectomy. Application of PEEP to intubated patients may also tamponade hemorrhage caused by a PAC [81].

Thromboembolic Complications

Because PACs constitute foreign bodies in the cardiovascular system and can potentially damage the endocardium, they are associated with an increased incidence of thrombosis. Thrombi encasing the catheter tip and aseptic thrombotic vegetations forming at endocardial sites in contact with the catheter have been reported [74]. Extensive clotting around the catheter tip can occlude the pulmonary vasculature distal to the catheter, and thrombi anywhere in the venous system or right heart can serve as a source of pulmonary emboli. Subclavian venous thrombosis, presenting with unilateral neck vein distention and upper extremity edema, may occur in up to 2% of subclavian placements [82]. Venous thrombosis complicating percutaneous internal jugular vein catheterization is fairly commonly reported, although its clinical importance remains uncertain. Consistently damped pressure tracings without evidence of peripheral catheter migration or pulmonary vascular occlusion should arouse suspicion of thrombi at the catheter tip. A changing relationship of PADP to PAOP over time should raise concern about possible pulmonary emboli.

If an underlying hypercoagulable state is known to exist, if catheter insertion was particularly traumatic, or if prolonged monitoring becomes necessary, one should consider cautiously anticoagulating the patient. Heparin-bonded catheters reduce thrombogenicity [44] and are commonly used. However, an important complication of heparin-bonded catheters is HIT [83]. Routine platelet counts are recommended for patients with heparin-bonded catheters in place. Because of the risk of HIT, some hospitals have abandoned the use of heparin-bonded catheters.

Rhythm Disturbances

Atrial and ventricular arrhythmias occur commonly during insertion of PACs [84]. Premature ventricular contractions occurred during 11% of the catheter insertions originally reported by Swan et al. [1].

Studies have reported advanced ventricular arrhythmias (three or more
consecutive ventricular premature beats) in approximately 30% to 60% of patients undergoing right heart catheterization [68,85,86]. Most arrhythmias are self-limited and do not require treatment, but sustained ventricular arrhythmias requiring treatment occur in 0% to 3% of patients [74,85,86]. Risk factors associated with increased incidence of advanced ventricular arrhythmias are acute myocardial ischemia or infarction, hypoxia, acidosis, hypocalcemia, and hypokalemia [85]. A right lateral tilt position (5-degree angle) during PAC insertion is associated with a lower incidence of malignant ventricular arrhythmias than is the Trendelenburg position.

Although the majority of arrhythmias occur during catheter insertion, arrhythmias may develop at any time after the catheter has been correctly positioned. These arrhythmias are caused by mechanical irritation of the conducting system and may be persistent. Ventricular ectopy may also occur if the catheter tip falls back into the RV outflow tract. Evaluation of catheter-induced ectopy should include a portable chest radiograph to evaluate catheter position and assessment of the distal lumen pressure tracing to ensure that the catheter has not slipped into the RV. Lidocaine may be used but is unlikely to ablate the ectopy because the irritant is not removed. If the arrhythmia persists after lidocaine therapy or is associated with hemodynamic compromise, the catheter should be removed. Catheter removal should be performed by physicians under continuous ECG monitoring, because the ectopy occurs almost as frequently during catheter removal as during insertion [87].

Right bundle branch block (usually transient) can also complicate catheter insertion [88]. Patients undergoing anesthesia induction, those in the early stages of acute anteroseptal myocardial infarction, and those with acute pericarditis appear particularly susceptible to this complication. Patients with preexisting left bundle branch block are at risk for developing complete heart block during catheter insertion, and some have advocated the insertion of a temporary transvenous pacing wire, a PAC with a pacing lumen, or pacing PAC with the pacing leads on the external surface of the catheter. However, use of an external transthoracic pacing device should be sufficient to treat this complication.

**Intracardiac Damage**

Damage to the right heart chambers, tricuspid valve, pulmonic valve, and their supporting structures as a consequence of PA catheterization has been reported [89–91]. The reported incidence of catheter-induced endocardial disruption detected by pathologic examination varies from 3.4% to 75% [92], but most studies suggest a range of 20% to 30% [90,91]. These lesions consist of hemorrhage, sterile thrombus, intimal
fibrin deposition, and nonbacterial thrombotic endocarditis. Their clinical significance is not clear, but there is concern that they may serve as a nidus for infectious endocarditis.

Direct damage to the cardiac valves and supporting chordae occurs primarily by withdrawal of the catheters while the balloon is inflated [1]. However, chordal rupture has been reported despite balloon deflation. The incidence of intracardiac and valvular damage discovered on postmortem examination is considerably higher than that of clinically significant valvular dysfunction.

Infections

Catheter-related septicemia (the same pathogen growing from blood and the catheter tip) was reported in up to 2% of patients undergoing bedside catheterization in the 1970s [93]. However, the incidence of septicemia related to the catheter appears to have declined in recent years, with a number of studies suggesting a septicemia rate of 0% to 1% [68,94]. In situ time of more than 72 to 96 hours significantly increases the risk of catheter-related sepsis. Right-sided septic endocarditis has been reported [95], but the true incidence of this complication is unknown. Becker et al. [89] noted two cases of left ventricular abscess formation in patients with PACs and Staphylococcus aureus septicemia. Incidence of catheter colonization or contamination varies from 5% to 20%, depending on the duration of catheter placement and the criteria used to define colonization [95,96]. In situ catheter-related bloodstream infection may be diagnosed by quantitative blood cultures.

Pressure transducers have also been identified as an occasional source of infection [97]. The chance of introducing infection into a previously sterile system is increased during injections for CO determinations and during blood withdrawal. Approaches to reduce the risk of catheter-related infection include use of a sterile protective sleeve and antibiotic bonding to the catheter [69,98]. Scheduled changes of catheters do not reduce the rate of infection [99].

Other Complications

Rare miscellaneous complications that have been reported include (a) hemodynamically significant decreases in pulmonary blood flow caused by balloon inflation in the central PA in postpneumonectomy patients with pulmonary hypertension in the remaining lung, (b) disruption of the catheter’s intraluminal septum as a result of injecting contrast medium under pressure [100], (c) artifactual production of a midsystolic click caused by a slapping motion of the catheter against the interventricular septum in a patient with RV strain and paradoxic septal motion [101], (d) thrombocytopenia secondary to heparin-bonded catheters [83], and (e)
dislodgment of pacing electrodes [102]. Multiple unusual placements of PACs have also been reported, including in the left pericardiophrenic vein, via the left superior intercostal vein into the abdominal vasculature, and from the superior vena cava through the left atrium and left ventricle into the aorta after open-heart surgery [103].
GUIDELINES FOR SAFE USE OF PULMONARY ARTERY CATHETERS

Multiple revisions and changes in emphasis to the original recommended techniques and guidelines have been published [66,104]. These precautions are summarized as follows:

1. Avoiding complications associated with catheter insertion.
   a. Inexperienced personnel performing insertions must be supervised. Many hospitals require that PACs be inserted by a fully trained intensivist, cardiologist, or anesthesiologist. Use of ultrasound guidance is recommended.
   b. Keep the patient as still as possible. Restraints or sedation may be required but the patient should be fully monitored with ECG and pulse oximetry.
   c. Strict sterile technique is mandatory. A chlorhexidine skin prep solution and maximum barrier precautions are recommended.
   d. Examine the postprocedure chest radiograph (or ultrasonography) for pneumothorax (especially after subclavian or internal jugular venipuncture) and for catheter tip position.

2. Avoiding balloon rupture.
   a. Always inflate the balloon gradually. Stop inflation if no resistance is felt.
   b. Do not exceed recommended inflation volume. At the recommended volume, excess air will automatically be expelled from a syringe with holes bored in it that is constantly attached to the balloon port. Maintaining recommended volume also helps prevent the accidental injection of liquids.
   c. Keep the number of inflation–deflation cycles to a minimum.
   d. Do not reuse catheters designed for single usage, and do not leave catheters in place for prolonged periods.
   e. Use carbon dioxide as the inflation medium if communication between the right and left sides of the circulation is suspected.

3. Avoiding knotting. Discontinue advancement of the catheter if entrance to right atrium, RV, or PA has not been achieved at distances anatomically anticipated from a given insertion site. If these distances
have already been significantly exceeded, or if the catheter does not withdraw easily, use fluoroscopy before attempting catheter withdrawal. Never pull forcefully on a catheter that does not withdraw easily.

4. Avoiding damage to pulmonary vasculature and parenchyma.
   a. Keep recording time of PAOP to a minimum, particularly in patients with pulmonary hypertension and other risk factors for PA rupture. Be sure the balloon is deflated after each PAOP recording. There is never an indication for continuous PAOP monitoring.

b. Constant pressure monitoring is required each time the balloon is inflated. It should be inflated slowly, in small increments, and must be stopped as soon as the pressure tracing changes to PAOP or damped.

c. If an occlusion is recorded with balloon volumes significantly less than the inflation volume recommended on the catheter shaft, withdraw the catheter to a position where full (or nearly full) inflation volume produces the desired trace.

d. Anticipate catheter tip migration. Softening of the catheter material with time, repeated manipulations, and cardiac motion make distal catheter migration almost inevitable.

   i. Continuous PA pressure monitoring is mandatory, and the trace must be closely watched for changes from characteristic PA pressures to those indicating a PAOP or damped tip position.

   ii. Decreases over time in the balloon inflation volumes necessary to attain occlusion tracings should raise suspicion regarding catheter migration.

   iii. Confirm satisfactory tip position with chest radiographs immediately after insertion and at least daily.

    e. Do not use liquids to inflate the balloon. They may prevent deflation, and their relative incompressibility may increase lateral forces and stress on the walls of pulmonary vessels.

    f. Hemoptysis is an ominous sign and should prompt an urgent diagnostic evaluation and rapid institution of appropriate therapy.

    g. Avoid injecting solutions at high pressure through the catheter lumen on the assumption that clotting is the cause of the damped pressure trace. First, aspirate from the catheter. Then consider problems related to catheter position, stopcock position, transducer dome, transducers, pressure bag, flush system, or trapped air bubbles. Never flush the catheter in the occlusion position.
5. Avoiding thromboembolic complications.
   a. Minimize trauma induced during insertion.
   b. Consider the judicious use of anticoagulants in patients with hypercoagulable states or other risk factors.
   c. Avoid flushing the catheter under high pressure.
   d. Watch for a changing PADP–PAOP relationship, as well as for other clinical indicators of pulmonary embolism.
5. Avoiding arrhythmias.
   a. Constant ECG monitoring during insertion and maintenance, as well as ready accessibility of all supplies for performing cardiopulmonary resuscitation, defibrillation, and temporary pacing, are mandatory.
   b. Use caution when catheterizing patients with an acutely ischemic myocardium or preexisting left bundle branch block.
   c. When the balloon is deflated, do not advance the catheter beyond the right atrium.
   d. Avoid over manipulation of the catheter.
   e. Secure the introducer in place at the insertion site.
   f. Watch for intermittent RV pressure tracings when the catheter is thought to be in the PA position. An unexplained ventricular arrhythmia in a patient with a PAC in place indicates the possibility of catheter-provoked ectopy.
7. Avoiding valvular damage.
   a. Avoid prolonged catheterization and excessive manipulation.
   b. Do not withdraw the catheter when the balloon is inflated.
5. Avoiding infections.
   a. Use meticulously sterile technique on insertion.
   b. Avoid excessive number of CO determinations and blood withdrawals.
   c. Avoid prolonged catheterization.
   d. Remove the catheter if signs of phlebitis develop. Culture the tip and use antibiotics as indicated.
Hemodynamic monitoring enhances the understanding of cardiopulmonary pathophysiology in critically ill patients. Nonetheless, the risk-to-benefit profile of PA catheterization in various clinical circumstances remains uncertain [105]. Large trials have concluded that there may be no outcome benefit to patients with PACs used as part of clinical decision-making [106]. There is concern that data obtained during PA catheterization may not be optimally used, or perhaps in specific groups may increase morbidity and mortality. A meta-analysis of 13 randomized clinical trials concluded that the use of the PAC neither increased overall mortality or hospital days, nor conferred any benefit. The authors concluded that despite nearly 20 years of randomized clinical trials involving the PA catheter, there has not been a clear strategy in its use which has led to improved survival [107].

Until the results of future studies are available, clinicians using hemodynamic monitoring should carefully assess the risk-to-benefit ratio on an individual patient basis. The operator should understand the indications, insertion techniques, equipment, and data that can be generated before undertaking PAC insertion. PA catheterization must not delay or replace bedside clinical evaluation and treatment.

Gastrointestinal (GI) endoscopy has evolved into an essential diagnostic and therapeutic tool for the treatment of patients in the intensive care unit (ICU). This chapter reviews general aspects of current indications and contraindications, provides an update of emerging technologies in the field, and concludes by discussing potential future directions.

PATIENT SELECTION

The indications for GI endoscopy in the ICU are summarized in Table 20.1. They are divided into those for (a) evaluation of the upper GI tract (esophagus, stomach, and duodenum); (b) evaluation of the pancreaticobiliary tract; (c) evaluation of the mid-GI tract (jejunum and ileum); and (d) evaluation of the lower GI tract (colon and rectum). In general, endoscopic interventions are contraindicated when the patient is hemodynamically unstable, when there is suspected perforation, or when adequate patient cooperation or consent cannot be obtained \[^1\]. Other contraindications are listed in Table 20.2.

**Evaluation of the Upper Gastrointestinal Tract**

Common indications for evaluation of the upper GI tract in the ICU include, but are not limited to, upper GI bleeding (UGIB), caustic or foreign body ingestion (FBI), placement of gastroduodenal stents for gastric outlet obstruction (GOO), and placement of feeding tubes for nutrition.

**Upper Gastrointestinal Bleeding**

With an estimated 400,000 admissions annually, acute UGIB presents as a common medical emergency with mortality rates as high as 16% in the ICU [2]. This condition is suspected in patients who present with melena, hematemesis, or blood in the nasogastric (NG) aspirate, as studies have shown improved outcomes with urgent endoscopic management in critically ill patients with hemodynamic instability or continuing transfusion requirements [3,4]. Urgent evaluation allows differentiation between nonvariceal (peptic ulcer, esophagitis, Mallory–Weiss tear, and angiodysplasia) and variceal lesions (esophageal or gastric varices),
thereby promoting targeted therapy [5]. Furthermore, urgent evaluation allows the identification and stratification of stigmata of bleeding, promoting appropriate triage and risk stratification. Finally, urgent evaluation allows the early identification of patients who may require surgical or invasive radiological intervention [3].

Foreign Body Ingestions

FBI can be divided into two groups: (i) food impaction and (ii) caustic ingestions. Food impactions constitute the majority of FBI. Although most will pass spontaneously, endoscopic removal will be needed for 10% to 20% of cases, and 1% of patients will ultimately require surgery [6]. Evaluation is crucial to determine the underlying cause of the obstruction (strictures, rings, and carcinoma). Although caustic ingestions constitute only a small number of FBI, they are frequently life threatening, especially when they occur intentionally in adults, and warrant endoscopic evaluation to prognosticate and triage this group of patients [7].

Endoscopic Stenting for Gastric Outlet Obstruction

Although GOO is typically managed conservatively with receiving nothing by mouth, intravenous (IV) fluids, and decompression with a NG tube, GOO secondary to a malignancy can be treated with an endoscopically placed stent. Often used as a palliative measure, duodenal self-expandable metal stents (SEMS) have been found effective in providing relief from obstructive symptoms, allowing patients to resume eating, and improving quality of life [8].

Feeding Tubes

Enteral nutrition is associated with improved outcomes for critically ill patients and is preferred over parenteral nutrition in patients with a functional GI tract [9]. Although nasoenteric and oroenteric feeding tubes may be used for short-term enteral nutrition, these tubes are felt to carry a higher risk of aspiration, displacement, and sinus infections than endoscopically placed percutaneous tubes. Percutaneous endoscopic gastrostomy (PEG) [10] is appropriate for most patients in the ICU when there is a reversible disease process likely to require more than 4 weeks of enteral nutrition (e.g., neurologic injury, tracheostomy, and neoplasms of the upper aerodigestive tract) [21]. PEG with a jejunostomy tube and
direct percutaneous endoscopic jejunostomy tubes are appropriate for selected patients in the ICU with high risk of aspiration. This includes patients with severe gastroesophageal reflux disease and those with gastroparesis. Enteral feeding beyond the ligament of Treitz with a nasojejunal tube or a jejunostomy tube has been demonstrated to be beneficial in patients with necrotizing pancreatitis, although a study demonstrated that there was no difference in mortality or infection rate between early, nasoenteric feeding and oral feeding 72 hours after admission in patients with acute pancreatitis [12]. Occasionally, endoscopic gastrostomies or jejunostomies may be indicated for decompression in patients with GI obstruction [13]. Although these procedures are technically simple and can be performed at the bedside under moderate sedation, the risks and benefits should always be weighed carefully in this critically ill group of patients.

Evaluation of the Pancreaticobiliary Tract

The indications for evaluation of the pancreaticobiliary tract by endoscopic retrograde cholangiopancreatography (ERCP) in critically ill patients are described in detail in Chapter 208 and only briefly discussed here. They include biliary tract obstruction by gallstones [14–16], pancreatic duct leaks, and bile duct leaks (generally a postoperative or traumatic complication) [17,18]. ERCP with sphincterotomy and/or stenting is the treatment of choice. When conventional ERCP is unsuccessful, the recent introduction of miniature endoscopes (cholangioscopes or pancreatic scopes) with direct endoscopic visualization into these ductal systems has proved to be beneficial through the use of advanced techniques such as electrohydraulic lithotripsy, laser lithotripsy, and topical glue [19]. Additionally, endoscopic necrosectomy for walled-off pancreatic necrosis via endoscopic ultrasound (EUS) has been validated as a viable alternative to surgical necrosectomy for this complication of pancreatitis [20].

Evaluation of the Mid-Gastrointestinal Tract (Jejunum and Ileum)

Persistent, GI bleeding without an identified site is the most common indication for mid-GI tract evaluation. Although this area of the GI tract had been difficult to evaluate in the past, this is no longer the case. The progression of video capsule endoscope (VCE), double-balloon enteroscopy (DBE), and spiral enteroscopy has made this area of the GI tract readily accessible. VCE is usually the first test performed to look for possible sites of bleeding in the jejunum and ileum (Fig. 20.1A and B). If bleeding or lesions are identified, DBE (Fig. 20.2) or the spiral endoscope
(Fig. 20.3) can be used to implement therapy.

Evaluation of the Lower Gastrointestinal Tract

Lower GI tract evaluation is urgently needed in ICU patients in cases of severe lower GI bleeding (LGIB), acute colonic distention, and at times of refractory diarrhea for the evaluation of infection, such as *Clostridium difficile* [21].

Lower Gastrointestinal Bleeding

Severe LGIB is predominantly a disease of the elderly. It is defined as bleeding from a source distal to the ligament of Treitz for less than 3 days [22]. Common causes include, but are not limited to, diverticular bleeding, ischemic colitis, and vascular abnormalities (arteriovenous malformations, AVMs). The site of bleeding is not always identified easily; as many as 11% of patients initially suspected of having a LGIB are ultimately found to have an UGIB [23]. Therefore, UGIB sources should always be considered first in patients with LGIB, particularly in patients with unstable hemodynamics. Once an upper GI source has been excluded, colonoscopy should be performed to evaluate the lower GI tract and administer appropriate therapy. Although urgent colonoscopy within 24 to 48 hours has shown to decrease the length of hospital stay [24] and endoscopic intervention is often successful, 80% to 85% of LGIBs stop spontaneously [25]. If the bleeding is severe or a source cannot be identified at colonoscopy, a technetium (TC)-99m red blood cell scan
Acute Colonic Distention

This condition can be caused by acute colonic obstruction or acute colonic pseudoobstruction. Acute colonic obstruction can be caused by neoplasms, diverticular disease, and volvulus [27]. Volvulus is a “closed-loop obstruction” and is considered an emergency because unlike the other causes of colonic obstruction, it can rapidly deteriorate from obstruction to ischemia, to perforation, and even result in death. However, if identified and treated early, it can be reversed. Acute colonic pseudoobstruction is a syndrome of massive dilation of the colon without mechanical obstruction that develops in hospitalized patients with serious underlying medical and surgical conditions due to impaired colonic motility. Increasing age, cecal diameter, delay in decompression, and status of the bowel significantly influence mortality, which is approximately 40% when ischemia or perforation is present. Evaluation of the markedly distended colon in the ICU setting involves excluding mechanical obstruction and other causes of toxic megacolon, such as *C. difficile* infection, and assessing for signs of ischemia and perforation. The risk of colonic perforation in acute colonic pseudoobstruction increases when cecal diameter exceeds 12 cm and when the distention has been present for greater than 6 days [28].
When endoscopic interventions are contemplated, for any of the previously discussed indications, a number of issues need to be addressed: appropriate resuscitation, reversal of coagulopathies, adequate sedation, and antibiotics, especially in patients with ascites or endocarditis who present with GI bleeding [29,30]. In selected cases, proper sedation may simply involve light sedation [31]. In other cases, such as in uncooperative, confused, or hypoxemic patients, proper sedation may require deep sedation or endotracheal intubation with general anesthesia. Although this type of sedation does not significantly alter the risk of acquired pneumonia or cardiovascular events [32], it does generate controlled conditions during the procedure and may help prevent massive aspiration (especially in patients with variceal bleeding).

In all patients with UGIB, an empty stomach is crucial for thorough evaluation and identification of the bleeding lesion. Through proper identification and treatment, studies have shown a reduction in the risk of rebleeding and in the need for surgical intervention [33]. Gastric lavage with an NG tube or through use of the endoscope can clear the stomach of blood and clot. At times, the use of prokinetic agents such as erythromycin (250 mg in 50 mL of normal saline IV, 20 minutes prior to the procedure) may also be helpful. Studies have in fact shown that this approach may improve the endoscopic visualization, improve the outcome, and decrease the need for “second-look” endoscopy [34].

If a variceal hemorrhage is suspected, on the basis of a clinical history or physical examination that suggests portal hypertension, adjunctive therapy should be initiated immediately in the absence of contraindications. Both somatostatin analogues (octreotide) or vasopressin and its analogues have been used IV to reduce portal pressures and prevent recurrent bleeding [35]. Octreotide is usually given as a onetime bolus of 50 to 100 μg IV, followed by 25 to 50 μg IV per hour for 3 to 5 days. In addition, prophylactic antibiotics should be given to patients with active esophageal variceal bleeding for the prevention of bacterial infections [36]. In contrast to nonvariceal hemorrhage, volume resuscitation should be performed judiciously in variceal bleeding as volume repletion can theoretically increase portal pressures. Unlike the other types of endoscopies discussed previously, this is the only one requiring a preprocedure bowel preparation. In urgent situations, this can be done through a technique known as a rapid purge. This technique is usually achieved by drinking 4 L or more polyethylene glycol–based solutions over a 2- to 3-hour period. Approximately one-third of hospitalized patients require an NG tube for this type of preparation [37].
Metoclopramide (10 mg IV × 1), administered prior to starting the preparation, may help to control nausea and promote gastric emptying [34].
INTRAPROCEDURAL CARE

Upper Gastrointestinal Endoscopy

Upper Gastrointestinal Bleeding

If the bleeding source is found to be a peptic ulcer, the intervention will depend on the specific endoscopic findings [38]. If the ulcer has a clean base with no signs of active bleeding, endoscopic intervention is not indicated. If an actively bleeding or a nonbleeding visible vessel is identified in the crater of the ulcer, endoscopic hemostatic techniques are recommended. A number of endoscopic methods have been developed for hemostasis, including injection therapy, thermal cautery therapy, and mechanical hemostasis with clips (Table 20.3). The combination of injection therapy with thermal coaptive therapy is superior to either alone [36,39]. Although no single solution for endoscopic injection therapy appears superior to another, an epinephrine–saline solution is usually injected in four quadrants surrounding the lesion. Heater probe and multipolar electrocoagulation instruments are subsequently applied with firm pressure to achieve optimal coaptation. Mechanical hemostasis with hemoclips have the advantage of minimal tissue damage, leading to potentially faster ulcer healing and it has been found effective for ulcer bleeding alone or in conjunction with other therapies (Fig. 20.4) [40].

Argon plasma coagulation is a noncoaptive technique that provides cautery to tissues by means of ionized argon gas. This method appears to be most effective for shallow and broadly defined bleeding lesions such as vascular ectasias, but has been found to be as effective in ulcer management as other common modalities [38]. The yttrium-aluminum-garnet laser has fallen out of favor in the acute management of high-risk patients because of its poor portability and associated high cost. Hemospray is a hemostatic powder (Cook Medical, Winston-Salem, NC) recently introduced for the management of GI bleeding that is both a cohesive and adhesive substance that creates a mechanical barrier. Applied in short bursts with carbon dioxide propulsion directly to the bleeding site, Hemospray is given until hemostasis is seen. It has been studied as both primary therapy and salvage therapy and has been shown to be effective in UGIB and LGIB [41,42]. Similarly, cryotherapy has gained wider recognition as it allows for tissue destruction via freezing by delivering a 25 to 30 mL per minute outflow of nitric monoxide at a temperature of −89.5°C and creating a 2 to 10 mm ice layer on the surface of the mucosa. It has found particular success in the management of angiodysplasia (AVM) [43].

**FIGURE 20.4** Hemostatic clip placed on an arteriovenous malformation in the proximal jejunum during a spiral enteroscopy.  
(Courtesy of David Cave, MD: Professor of Medicine, University of Massachusetts Medical School.)
In the last several years, several other modalities have emerged as effective treatment methods in UGIB. The over-the-scope-clip (OTSC) system, first developed in Germany, is a device that can be used to achieve hemostasis and close perforations, fistulas, or anastomotic leaks. Similar to the esophageal banding device, the OTSC cap can be loaded onto the tip of the scope, which can then be placed over the lesion, sucking the lesions in and allowing for the clip to be deployed. This device has now been studied in many different indications, and has enjoyed success in cases refractory to traditional hemostatic methods [44,45].

EUS has now been incorporated into the management of refractory GI bleeding. Under EUS visualization of a bleeding vessel with Doppler, the vessel is punctured with a 19-gauge needle and injected with a sclerosing agent such as cyanoacrylate (glue) or coils. Doppler monitoring then allows for viewing of the disappearance of the Doppler signal, signaling the cessation of bleeding. This method of EUS-guided angiotherapy has found success in a variety of bleeding etiologies, including gastric varices, ulcers, and malignancy [46].

In esophageal variceal bleeding, endoscopic variceal ligation (EVL) has become the procedure of choice [47,48]. With this technique, the varix is suctioned into a banding device attached to the tip of the endoscope and a rubber band is then deployed at its base to obliterate the varix. In contrast, endoscopic sclerotherapy (EST) causes obliteration by injection of a sclerosing agent (e.g., sodium morrhuate) in or around the bleeding varix. A meta-analysis by Laine and Cook [48] suggested that EVL was superior to EST in all major outcomes (recurrent bleeding, local complications such as ulcers or strictures, time to variceal obliteration, and survival). However, EST is effective in controlling active bleeding in more than 90% of cases and can be injected even with poor visualization during an active bleed.

Endoscopic methods (EST, EVL, and injection of fibrin glue) have also been used for the treatment of bleeding gastric varices. These methods, however, carry a considerable risk of rebleeding and mortality. Patients with bleeding gastric varices generally require urgent placement of a transjugular intrahepatic portosystemic shunt [49]. Balloon-occluded retrograde transvenous obliteration, a procedure first developed in Asia, has slowly been introduced in the United States, and consists of retrograde injection of sclerosing agents into gastric varices after balloon occlusion of the gastrorenal shunt, taking advantage of the tendency of gastric fundal varices to drain into the left renal vein via a gastrorenal shunt. Given its high success rate, this procedure represents another viable method to treat gastric varices [50].
**Enteral Stents**

The use of uncovered SEMS has been widely studied for use in GOO secondary to a malignancy. As long as a guidewire is able to be passed through the obstruction, the stent can be placed onto the guidewire and advanced under fluoroscopic guidance. A large systematic review demonstrated that there were no significant differences between the stent placement and surgical gastrojejunostomy in technical success, complications, or persistent of symptoms [51]. Stent placement, however, did have a higher rate of recurrent obstructive symptoms (18% vs. 1%) and decreased mean survival (105 vs. 164 days). Despite this, enteral stent placement does have a 90% initial clinical success rate, and should be pursued for palliative purposes in patients with a less than 6-month life expectancy.

**Enteric Feeding Tubes**

Please see Chapter 21 for more details on the placement of enteric feeding tubes.

**Pancreaticobiliary Endoscopy**

Refer to Chapter 208.

**Small Bowel Endoscopy**

The techniques are essentially the same as those for upper GI endoscopy (above).

**Lower Gastrointestinal Endoscopy**

**Lower Gastrointestinal Bleeding**

The endoscopic treatment options for LGIB are similar to those for UGIB (see earlier in the chapter) and should be based on the stigmata of bleeding that are identified. Hemostasis is usually approached through a combination approach of injection therapy with clipping or coagulation therapy.

**Decompressive Endoscopy**

A water-soluble contrast enema or computed tomography should be the initial procedure to perform in patients with acute colonic distention.
This will establish the presence or absence of mechanical obstruction. Subsequently, the patient should undergo resuscitation with IV fluids, frequent repositioning, NG and rectal tube placements, correction of metabolic imbalances, and discontinuation of medications known to slow intestinal transit [52]. If conservative measures are unsuccessful, decompressive endoscopy with minimal inflation of air resolves acute obstruction of the colon in the majority of cases (81%) [53]. Despite a high recurrence rate (23% to 57%), colonoscopy is often considered the initial procedure of choice in the absence of intestinal ischemia [54]. This may be reduced with the placement of a decompression tube beyond the splenic flexure [55]. In patients with mechanical obstruction, SEMS can be placed with good outcome [56]. In patients with nonmechanical obstruction, medical therapy with the parasympathomimetic agent neostigmine should be considered. On the basis of a double-blind, placebo-controlled, randomized trial, the parasympathomimetic agent neostigmine has been shown to reduce colonic distention significantly, reduce recurrence, with minimal risk [57]. This agent should only be given in the absence of contraindications and under close cardiorespiratory monitoring with atropine at the bedside. Percutaneous, endoscopic, or surgical cecostomy presents another alternative if the aforementioned interventions are unsuccessful.

**Fecal Microbiota Transplantation**

The increase in prevalence of *Clostridium difficile* infection (CDI) and particularly recurrent CDI has brought fecal microbiota transplantation (FMT) to the forefront. Numerous studies have demonstrated its high success rate, but it remains poorly studied in cases of severe CDI, which will often require ICU care [58]. Nevertheless, the ability to perform FMT via upper endoscopy, colonoscopy, and rectal enema presents an alternative treatment option in patients with CDI who have failed conventional antibiotic therapy.

**Perforations, Fistulas, and AnastamoticLeaks**

Recently, the OverStitch (Apollo Endosurgery Inc., Austin, TX) has emerged as an endoscopic suturing device that can also be used to closing perforations and fistulas (Fig. 20.5). This system is attached to a standard endoscope and allows for a detachable needle to be used to suture lesions with a suture-cinching tool used to secure the deployed suture [59,60]. This may represent a method to close small perforations and fistulas without the need for surgical intervention.
POST-PROCEDURAL CARE

Although major complications of endoscopic procedures are infrequent, critically ill patients may be particularly sensitive to adverse outcomes due to multiple comorbidities. It is crucial to monitor patients for complications post procedures. These can be divided into two groups: (i) general complications and (ii) specific complications (Table 20.4).

</table>

In patients with UGIB, post procedure pharmacotherapy is also indicated. In patients with nonvariceal UGIB, for example, antisecretory therapy with a proton pump inhibitor (PPI) following endoscopic hemostasis is encouraged [40]. IV administration of a PPI is a faster way to achieve gastric acid suppression than is oral administration of the same agent. Peak suppression after IV administration occurs within hours, compared with several days later after oral administration. This is crucial because it can reduce the risk of rebleeding and the need for surgery [40]. The PPIs currently approved for IV use in the United States include pantoprazole, lansoprazole, and esomeprazole. In contrast, patients with variceal UGIB should receive daily nonselective β-blockers for secondary prevention in addition to repeat EVL every 3 to 4 weeks until obliteration of the varices is achieved [61].
FUTURE DIRECTIONS

The constantly evolving landscape of endoscopic technologies and methods will continue to expand the reach of endoscopic intervention. One area in particular is the developing role of endoscopic suturing in the GI tract, especially in the care and management of mucosal perforation, in the treatment of GI bleeding, and the closure of fistulas. Although case reports are in the literature, larger studies are needed before this technique can be recommended on a regular basis. Other areas of development are the evaluation and management of small bowel bleeding. With the advent of viewers linked in to video capsule and the development of the power spiral endoscopy, this may allow earlier recognition and treatment of small bowel disease than thought previously; however, studies are needed to determine the efficacy and benefits of these techniques.
REFERENCES

Indications for Enteral Feeding

Nutritional support is an essential component of intensive care medicine (see Chapters 212–214).

National and international guidelines [1–4] and comprehensive reviews [5] all strongly recommend that enteral nutrition be used in preference to parenteral nutrition when possible.

Provision of nutrition through the enteral route aids in prevention of gastrointestinal mucosal atrophy, thereby maintaining the integrity of the gastrointestinal mucosal barrier. Other advantages of enteral nutrition are preservation of immunologic gut functions and normal gut flora, improved use of nutrients, and reduced costs. Some studies suggest that clinical outcomes are improved and infectious complications are less frequent in patients who receive enteral nutrition compared with parenteral nutrition.

Although there are absolute or relative contraindications to enteral feeding in selected cases, most critically ill patients can receive some or all of their nutritional requirements via the gastrointestinal tract. Enteral feeding is even recommended in severe acute pancreatitis, and nasogastric or nasojejunal feedings are both well tolerated [6]. Even when some component of nutritional support must be provided by parenteral nutrition, feeding via the gut is desirable.

Several developments—including new techniques for placement of feeding tubes, availability of smaller caliber, minimally reactive tubes, and an increasing range of enteral formulas—have expanded the ability to provide enteral nutritional support to critically ill patients. Relative or absolute contraindications to enteral feeding include fistulas, intestinal obstruction, upper gastrointestinal hemorrhage, and severe inflammatory...
bowel disease or intestinal ischemia. Enteral feeding is not recommended in patients with severe malabsorption or early in the course of severe short-gut syndrome.
ACCESS TO THE GASTROINTESTINAL TRACT

After deciding to provide enteral nutrition, the clinician must decide whether to deliver the formula into the stomach, duodenum, or jejunum, and determine the optimal method for accessing the site, which is based on the function of the patient’s gastrointestinal tract, duration of enteral nutritional support required, and risk of pulmonary aspiration. Gastric feeding provides the most normal route for enteral nutrition, but may not be tolerated in the critically ill patient because of gastric dysmotility with delayed emptying [7]. Enteral nutrition infusion into the duodenum or jejunum may decrease the incidence of aspiration because of the protection afforded by a competent pyloric sphincter; however, the risk of aspiration is not completely eliminated by feeding distal to the pylorus [8–10]. An advantage of this site of administration is that enteral feeding can be initiated early in the postoperative period, because postoperative ileus primarily affects the colon and stomach and only rarely involves the small intestine.
TECHNIQUES

Enteral feeding tubes can be placed via the transnasal, transoral, or percutaneous transgastric or transjejunal routes. If these procedures are contraindicated or unsuccessful, the tube may be placed by endoscopy, using endoscopic and laparoscopic technique, or surgically via a laparotomy [11].

Nasoenteric Route

Nasoenteric tubes are the most commonly used means of providing enteral nutritional support in critically ill patients. This route is preferred for short- to intermediate-term enteral support when eventual resumption of oral feeding is anticipated. It is possible to infuse enteral formulas into the stomach using a conventional 16- or 18-French (Fr) polyvinyl chloride nasogastric tube, but patients are usually much more comfortable if a small-diameter silicone or polyurethane feeding tube is used. Nasoenteric tubes vary in luminal diameter (6 to 14 Fr) and length, depending on the desired location of the distal orifice: stomach, 30 to 36 inches; duodenum, 43 inches; jejunum, at least 48 inches. Some tubes have tungsten-weighted tips designed to facilitate passage into the duodenum via normal peristalsis, whereas others have a stylet. Most are radiopaque. Some tubes permit gastric decompression while delivering formula into the jejunum.

Nasoenteric feeding tubes should be placed with the patient in a semi-Fowler’s or sitting position. The tip of the tube should be lubricated, placed in the patient’s nose, and advanced to the posterior pharynx. If the patient is alert and can follow instructions, the patient should be permitted to sip water as the tube is slowly advanced into the stomach. To avoid unintentional airway placement and serious complications, position of the tube should be ascertained after it has been inserted to 30 cm. Acceptable means of documenting intraesophageal location of the tube include a chest radiograph or lack of CO₂ detection through the lumen of the tube by capnography or colorimetry. If the tube is in the airway, CO₂ will be detected and the tube must be removed. Alternatively, commercial systems are now available to track tube progression from the esophagus through the stomach to the duodenum by electromagnetic means. Proper final placement of the tube in the stomach must be confirmed by chest or upper abdominal radiograph before tube feeding is begun. The following methods to assess final tube placement are unreliable and do not assess tube misdirection into the lower respiratory tract: auscultation over the left upper quadrant with air insufflation
through the tube, assessment of pH with gastric content aspiration, and easy passage of the tube to its full length with the absence of gagging and coughing [12]. The tube should be securely taped to the nose, forehead, or cheek without tension. Nasal bridles are more effective at securing nasoenteric tubes than use of tape [13].

Delayed gastric emptying has been confirmed in critically ill patients and may contribute to gastric feeding intolerance. Spontaneous transpyloric passage of enteral feeding tubes in critically ill patients is commonly unsuccessful, secondary to the preponderance of gastric atony. The addition of a tungsten weight to the end of enteral feeding tubes and the development of wire or metal stylets in enteral feeding tubes are aimed at improving the success rate for spontaneous transpyloric passage. Once the tube is documented to be in the stomach, various bedside techniques, including air insufflation, pH-assisted, magnet-guided and spontaneous passage with or without motility agents, may help facilitate transpyloric feeding tube passage.

Intravenous (IV) metoclopramide and erythromycin have been recommended as prokinetic agents. But a Cochrane Database Systematic Review concluded that doses of 10 or 20 mg of IV metoclopramide were equally ineffective in facilitating transpyloric feeding tube placement [14]. No matter which techniques are used to facilitate transpyloric passage of enteral feeding tubes, these tubes must be inserted by skilled practitioners using defined techniques.

If the tube does not pass into the duodenum on the first attempt, placement can be attempted under endoscopic assistance or fluoroscopic or electromagnetic guidance. The latter method requires specialized equipment. Endoscopic placement of nasoenteral feeding tubes is easily accomplished in the critically ill patient and can be performed at the bedside using portable equipment [15]. Transnasal or transoral endoscopy can be used for placement of nasoenteral feeding tubes in critically ill patients. The patient is sedated appropriately (see Chapter 20), and topical anesthetic is applied to the posterior pharynx with lidocaine or benzocaine spray. A 43- to 48-inches-long nasoenteric feeding tube with an inner wire stylet is passed transnasally into the stomach. The endoscope is inserted and advanced through the esophagus into the gastric lumen. An endoscopy forceps is passed through the biopsy channel of the endoscope and used to grasp the tip of the enteral feeding tube. The endoscope, along with the enteral feeding tube, is advanced distally into the duodenum as far as possible (Fig. 21.1).
FIGURE 21.1 Endoscopic placement of nasoenteral feeding tube. Endoscopy forceps and gastroscope advance the feeding tube in the duodenum.

The endoscopy forceps and feeding tube remain in position in the distal duodenum as the endoscope is withdrawn back into the gastric lumen. The endoscopy forceps are opened, the feeding tube released, and the endoscopy forceps withdrawn carefully back into the stomach. On first pass, the feeding tube is usually lodged in the second portion of the duodenum. The portion of the feeding tube that is redundant in the stomach is advanced slowly into the duodenum using the endoscopy forceps to achieve a final position distal to the ligament of Treitz (Fig. 21.2). An abdominal radiograph is obtained at the completion of the procedure to document the final position of the nasoenteral feeding tube. Endoscopic placement of postpyloric enteral feeding tubes is highly successful, eliminates the risk of transporting the patient to the radiology department for fluoroscopic placement, and allows prompt achievement of nutritional goals, because enteral feeding can be initiated immediately after the procedure.
The recent development of ultrathin endoscopes (outer diameter 5.1 to 5.9 mm vs. 9.8 mm in standard gastroscope) has enabled nasoenteric feeding tube placement via transnasal endoscopy using an over-the-wire technique. A 90% success rate was documented with endoscopic procedure duration of approximately 13 minutes, shorter than fluoroscopic procedure duration, and without the need for additional sedation [16]. Transnasal ultrathin endoscopy without the need for sedation can also be used for feeding tube or percutaneous endoscopic gastrostomy (PEG) placement in patients who are unable to undergo transoral endoscopy, that is, those who have partial or complete occlusion of the mouth [17].
Electromagnetic guidance employs a feeding tube with a guidewire that emits electromagnetic waves. A box with three receivers that is placed on the patient’s xiphoid process triangulates the position of the tube. The clinician is able to “view” the tip on a monitor as it passes down the esophagus through the stomach and into the duodenum. An X-ray is still required to confirm and document tube placement.

**Percutaneous Route**

PEG tube placement, introduced by Ponsky et al. [18] in 1990, has become the procedure of choice for patients requiring prolonged enteral nutritional support. PEG tubes range in size from 20 to 28 Fr. PEG rapidly replaced open gastrostomy as the method of choice for enteral nutrition. Unlike surgical gastrostomy, PEG does not require general anesthesia and laparotomy and eliminates the discomfort associated with chronic nasoenteric tubes. This procedure can be considered for patients who have normal gastric emptying and low risk for pulmonary aspiration, and can be performed in the operating room, in an endoscopy unit, or at the bedside in the intensive care unit with portable endoscopy equipment.

PEG should not be performed in patients with near or total obstruction of the pharynx or esophagus, in the presence of coagulopathy, or when transillumination is inadequate. Relative contraindications are ascites, gastric cancer, and gastric ulcer. Previous abdominal surgery is not a contraindication. The original method for PEG was the pull technique; more recent modifications are the push and introducer techniques.

**Pull Technique**

The pull technique is performed with the patient in the supine position. After a time-out, the abdomen is prepared and draped. The posterior pharynx is anesthetized with a topical spray or solution (e.g., benzocaine spray or viscous lidocaine), and IV sedation (e.g., 1 to 2 mg of midazolam; see Chapter 20) is administered. A prophylactic antibiotic, usually a first-generation cephalosporin, is administered before the procedure. The fiberoptic gastroscope is inserted into the stomach, which is then insufflated with air. The lights are dimmed, and the assistant applies digital pressure to the anterior abdominal wall in the left subcostal area approximately 2 cm below the costal margin, looking for the brightest transillumination (light reflex). The endoscopist should be able to clearly identify the indentation in the stomach created by the assistant’s digital
pressure on the anterior abdominal wall (digital reflex); otherwise, another site should be chosen.

When the correct spot has been identified, the assistant anesthetizes the anterior abdominal wall. The endoscopist then introduces a polypectomy snare through the endoscope. A small incision is made in the skin, and the assistant introduces a large-bore catheter–needle stylet assembly into the stomach and through the snare. The snare is then tightened securely around the catheter. The inner stylet is removed, and a looped insertion wire is introduced through the catheter and into the stomach. The cannula is slowly withdrawn so that the snare grasps the wire. The gastroscope is then pulled out of the patient’s mouth with the wire firmly grasped by the snare. The endoscopist guides the lubricated gastrostomy tube into the posterior pharynx and the esophagus. With continued traction, the gastrostomy tube is pulled into the stomach so that it exits on the anterior abdominal wall. The gastroscope is reinserted into the stomach to confirm adequate placement of the gastrostomy tube against the gastric mucosa and to document that no bleeding has occurred. The intraluminal portion of the tube should contact the mucosa, but excessive tension on the tube should be avoided because this can lead to ischemic necrosis of the gastric wall. The tube is secured to the abdominal wall using sutures. Feedings may be initiated immediately after the procedure or 24 hours later.

**Push Technique**

The push technique is similar to the pull technique. The gastroscope is inserted and a point on the anterior abdominal wall localized, as for the pull technique. Rather than introducing a looped insertion wire, however, a straight guidewire is snared and brought out through the patient’s mouth by withdrawing the endoscope and snare together. A commercially developed gastrostomy tube (Sachs–Vine) with a tapered end is then passed in an aboral direction over the wire, which is held taut. The tube is grasped and pulled out the rest of the way. The gastroscope is reinserted to check the position and tension on the tube.

**Introducer Technique**

The introducer technique uses a peel-away introducer technique originally developed for the placement of cardiac pacemakers and central venous catheters. The gastroscope is inserted into the stomach, and an appropriate position for placement of the tube is identified. After
infiltration of the skin with local anesthetic, a 16- or 18-gauge needle is introduced into the stomach. A J-tipped guidewire is inserted through the needle into the stomach, and the needle is withdrawn. Using a twisting motion, a 16-Fr introducer with a peel-away sheath is passed over the guidewire into the gastric lumen [19,20]. The guidewire and introducer are removed, leaving in place the sheath that allows placement of a 14-Fr Foley catheter. The sheath is peeled away after the balloon is inflated with 10 mL of normal saline. Some advocate this as the optimal method for PEG in patients with head and neck cancer, related to an overall lower rate of complications in this patient population [21].

Percutaneous Endoscopic Gastrostomy/Jejunostomy

If postpyloric feeding is desired, a PEG/jejunostomy may be performed. The tube allows simultaneous gastric decompression and duodenal/jejunal enteral feeding [22]. A second, smaller feeding tube can be attached and passed through the gastrostomy tube and advanced endoscopically into the duodenum or jejunum. When the PEG is in position, a guidewire is passed through it and grasped using endoscopy forceps. The guidewire and endoscope are passed into the duodenum as distally as possible. The jejunal tube is then passed over the guidewire through the PEG into the distal duodenum, advanced into the jejunum, and the endoscope is withdrawn. An alternative method is to grasp a suture at the tip of the feeding tube or the distal tip of the tube itself and pass the tube into the duodenum, using forceps advanced through the biopsy channel of the endoscope. This obviates the need to pass the gastroscope into the duodenum, which may result in dislodgment of the tube when the endoscope is withdrawn.

Direct Percutaneous Endoscopic Jejunostomy

Jejunostomy tubes can be placed endoscopically by means of a PEG with jejunal extension (PEG-J) or by direct percutaneous jejunostomy (PEJ) [23]. Because the size of the jejunal extension of the PEG-J tube is significantly smaller than that of the direct PEJ, some have suggested that the PEJ provides more stable jejunal access for those who require long-term jejunal feeding. Unfortunately, a low success rate (68%) and a high adverse event rate (22.5%) have been documented in the largest series to date [24]. New methods using balloon-assisted enteroscopy with fluoroscopy have improved technical success rates to 96% [25].
Fluoroscopic Technique

Percutaneous gastrostomy and gastrojejunostomy can also be performed using fluoroscopy [26,27]. The stomach is insufflated with air using a nasogastric tube or a skinny needle if the patient is obstructed proximally. Once the stomach is distended and position is checked again with fluoroscopy, the stomach is punctured with an 18-gauge needle. T-fastener gastropexy may be used, deployed via the 18-gauge needle. A heavy-duty wire is passed, and the tract is dilated to accommodate a gastrostomy or gastrojejunostomy tube.

Complications

The most common complication after percutaneous placement of enteral feeding tubes is infection, usually involving the cutaneous exit site and surrounding tissue [28]. Gastrointestinal hemorrhage has been reported, but it is usually caused by excessive tension on the tube, leading to necrosis of the stomach wall. Gastrocolic fistulas, which develop if the colon is interposed between the anterior abdominal wall and the stomach when the needle is introduced, have been reported. Adequate transillumination aids in avoiding this complication. Separation of the stomach from the anterior abdominal wall can occur, resulting in peritonitis when enteral feeding is initiated. In most instances, this complication is caused by excessive tension on the gastrostomy tube. Another potential complication is pneumoperitoneum, secondary to air escaping after puncture of the stomach during the procedure, and is usually clinically insignificant. If the patient develops fever and abdominal tenderness, a Gastrografin study should be obtained to exclude the presence of a leak.

All percutaneous gastrostomy and jejunostomy procedures described here have been established as safe and effective. The method is selected on the basis of the endoscopist’s experience and training and the patient’s nutritional needs.
SURGICAL PROCEDURES

Since the advent of PEG, surgical placement of enteral feeding tubes is usually performed as a concomitant procedure as the last phase of a laparotomy performed for another indication. Occasionally, an operation solely for tube placement is performed in patients requiring permanent tube feedings when a percutaneous approach is contraindicated or unsuccessful. In these cases, the laparoscopic approach to enteral access should be considered. Laparoscopic gastrostomy was introduced in 2000, 10 years after the advent of PEG. Patients who are not candidates for PEG, as a result of head and neck cancer, esophageal obstruction, large hiatal hernia, gastric volvulus, or overlying intestine or liver, should be considered for laparoscopic gastrostomy or jejunostomy.

Gastrostomy

Gastrostomy is a simple procedure when performed as part of another intra-abdominal operation. It should be considered when prolonged enteral nutritional support is anticipated after surgery. Complications are quite common after surgical gastrostomy. This may reflect the poor nutritional status and associated medical problems in many patients who undergo this procedure. Potential complications include wound infection, dehiscence, gastrostomy disruption, internal or external leakage, gastric hemorrhage, and tube migration.

Needle–Catheter Jejunostomy

The needle–catheter jejunostomy procedure consists of the insertion of a small (5-Fr) polyethylene catheter into the small intestine at the time of laparotomy for another indication. Kits containing the necessary equipment for the procedure are available from commercial suppliers. A needle is used to create a submucosal tunnel from the serosa to the mucosa on the antimesenteric border of the jejunum. A catheter is inserted through the needle and then the needle is removed. The catheter is brought out through the anterior abdominal wall, and the limb of the jejunum is secured to the anterior abdominal wall with sutures. The tube can be used for feeding immediately after the operation. The potential complications are similar to those associated with gastrostomy, but patients may have a higher incidence of diarrhea. Occlusion of the needle–catheter jejunostomy is common because of its small luminal diameter, and elemental nutritional formulas are preferentially used.
**Transgastric Jejunostomy**

Critically ill patients who undergo laparotomy commonly require gastric decompression and a surgically placed tube for enteral nutritional support. Routine placement of separate gastrostomy and jejunostomy tubes is common in this patient population and achieves the objective of chronic gastric decompression and early initiation of enteral nutritional support through the jejunostomy. Technical advances in surgically placed enteral feeding tubes led to the development of transgastric jejunostomy [29] and duodenostomy tubes, which allow simultaneous decompression of the stomach and distal feeding into the duodenum or the jejunum. The advantage of these tubes is that only one enterotomy into the stomach is needed, eliminating the possible complications associated with open jejunostomy tube placement. In addition, only one tube is necessary for gastric decompression and jejunal feeding, eliminating the potential complications of two separate tubes for this purpose.

The transgastric jejunostomy tube is placed surgically in the same manner as a gastrostomy tube, and the distal portion of the tube is advanced manually through the pylorus into the duodenum, with its final tip resting as far distally as possible in the duodenum or the jejunum (Fig. 21.3). The transgastric jejunostomy tube is preferred to transgastric duodenostomy tube because it is associated with less reflux of feedings into the stomach and a decreased risk of aspiration pneumonia. Surgical placement of transgastric jejunostomy tubes at the time of laparotomy is recommended for patients who likely require prolonged gastric decompression and enteral feeding.
FIGURE 21.3 Transgastric duodenal feeding tube, which allows simultaneous gastric decompression and duodenal feeding, can be placed percutaneously (with endoscopic or fluoroscopic assistance) or surgically.
DELIVERING THE TUBE-FEEDING FORMULA

The enteral formula can be delivered by intermittent bolus feeding, gravity infusion, or continuous pump infusion. In the intermittent bolus method, the patient receives 300 to 400 mL of formula every 4 to 6 hours. The bolus is usually delivered with the aid of a catheter-tipped, large-volume (60-mL) syringe. The main advantage of bolus feeding is simplicity. This approach is often used for patients requiring prolonged supplemental enteral nutritional support after discharge from the hospital. Bolus feeding can be associated with serious side effects, including gastric distention, nausea, cramping, and aspiration. The intermittent bolus method should not be used when feeding into the duodenum or the jejunum because boluses of formula can cause distention, cramping, and diarrhea.

Gravity-infusion systems allow the formula to drip continuously during 16 to 24 hours or intermittently during 20 to 30 minutes, four to six times per day. This method requires constant monitoring because the flow rate can be extremely irregular. The main advantages of this approach are simplicity, low cost, and close simulation of a normal feeding pattern.

Continuous pump infusion is the preferred method for the delivery of enteral nutrition in the critically ill patient. A peristaltic pump can be used to provide a continuous infusion of formula at a precisely controlled flow rate, which decreases problems with distention and diarrhea. Gastric residuals tend to be smaller with continuous pump-fed infusions, and the risk of aspiration may be decreased.
MEDICATIONS

When medications are administered via an enteric feeding tube, it is important to be certain that the drugs are compatible with each other and with the enteral formula. In general, medications should be delivered separately rather than as a combined bolus. For medications that are better absorbed in an empty stomach, tube feedings should be suspended for 30 to 60 minutes before administration.

Medications should be administered in an elixir formulation via enteral feeding tubes, whenever possible, to prevent occlusion of the tube. Enteral tubes should always be flushed with 20 mL of saline after medications are administered. To use an enteral feeding tube to administer medications dispensed in tablet form, often the pills must be crushed and delivered as slurry mixed with water. This is inappropriate for some medications, however, such as those absorbed sublingually or formulated as a sustained-released tablet or capsule.
COMPLICATIONS

Enteral tube placement is associated with few complications if practitioners adhere to appropriate protocols and pay close attention to the details of the procedures [30].

Nasopulmonary Intubation

Passage of an enteral feeding tube into the tracheobronchial tree most commonly occurs in patients with diminished cough or gag reflexes as a result of obtundation, altered mental status, or other causes such as the presence of endotracheal intubation. The presence of a tracheostomy or an endotracheal tube does not guarantee proper placement. A chest (or upper abdominal) radiograph should always be obtained before initiating tube feedings with a new tube to ensure that the tube is properly positioned. Endotracheal or transpulmonary placement of a feeding tube can be associated with pneumothorax, hydrothorax, pneumonia, pulmonary hemorrhage, abscess formation, or death [31]. A chest radiograph or a means of detecting CO$_2$ through the tube after it has been inserted 30 cm should be obtained to prevent unintentional placement of small-bore feeding tubes into the lungs. Alternatively, electromagnetic guidance can reduce the risk in intrapulmonary placement.

Aspiration

Pulmonary aspiration is a serious and potentially fatal complication of enteral nutritional support. The incidence of this complication varies and depends on the patient population studied. Traditional clinical monitors of aspiration with glucose oxidase strips and blue food coloring should no longer be used [32]. Nonrecumbent positioning is an evidence-based method for aspiration prevention that needs to be initiated in all patients receiving enteral nutrition.

Major risk factors for aspiration include obtundation or altered mental status, absence of cough or gag reflexes, delayed gastric emptying, gastroesophageal reflux, persistently high gastric residual volumes, and feeding in the supine position. The risk of pulmonary aspiration is minimized when the enteral feeding tube is positioned in the jejunum past the ligament of Treitz.
Gastrointestinal Intolerance

Delayed gastric emptying is sometimes improved by administering prokinetic agents. Combination therapy (metoclopramide 10 mg IV every 6 hours and erythromycin 200 mg IV every 12 hours) was highly effective compared to either agent alone for feeding intolerance in critical illness [33]. Dumping syndrome (i.e., diarrhea, distention, and abdominal cramping) can limit the use of enteral feeding. Dumping may be caused by delivering a hyperosmotic load into the small intestine.

Diarrhea in critically ill patients should not be attributed to intolerance of enteral feeding until other causes are excluded. Other possible etiologies for diarrhea include medications (e.g., magnesium-containing antacids and sorbitol-containing medications), alterations in gut microflora owing to prolonged antibiotic therapy, antibiotic-associated colitis, ischemic colitis, viral or bacterial enteric infection, electrolyte abnormalities, and excessive delivery of bile salts into the colon. Diarrhea can also be a manifestation of intestinal malabsorption because of enzyme deficiencies or villous atrophy [34].

Even if diarrhea is caused by enteral feeding, it can be controlled in nearly 50% of cases by instituting a continuous infusion of formula (if bolus feedings are used), slowing the rate of infusion, changing the formula (lower calorie, more elemental), adding fiber to the enteral formula, or adding antidiarrheal agents (e.g., loperamide, diphenoxylate/atropine, or tincture of opium).

Metabolic Complications

Prerenal azotemia and hypernatremia can develop in patients fed with hyperosmolar solutions. The administration of free water, either added to the formula or as separate boluses to replace obligatory losses, can avert this situation. Deficiencies of essential fatty acids and fat-soluble vitamins can develop after prolonged support with enteral solutions that contain minimal amounts of fat. Periodic enteral supplementation with linoleic acid or IV supplementation with emulsified fat can prevent this. The amount of linoleic acid necessary to prevent chemical and clinical fatty acid deficiency has been estimated to be 2.5 to 20.0 g per day.

Bacterial Contamination

Bacterial contamination of enteral solutions occurs when commercial packages are opened and mixed with other substances, and more commonly, it occurs with hospital-formulated and powdered feeds that require preparation compared to commercially prepared, ready-to-feed enteral formulas supplied in cans. The risk of contamination also
depends on the duration of feeding. Contaminated formula may also play a significant role in the etiology of diarrhea in patients receiving enteral nutrition.

Occluded Feeding Tubes

Precipitation of certain proteins when exposed to an acid pH may be an important factor leading to the solidifying of formulas. Most premixed intact protein formulas solidify when acidified to a pH less than 5. To prevent occlusion of feeding tubes, the tube should be flushed with water before and after checking residuals. Small-caliber nasoenteric feeding tubes should be flushed with 20 mL of water every 4 to 6 hours to prevent tube occlusion, even when enteral feedings are administered by continuous infusion.

Medications are a frequent cause of clogging [35]. When administering medications enterally, liquid elixirs should be used, if available, because even tiny particles of crushed tablets can occlude the distal orifice of small-caliber feeding tubes. If tablets are used, it is important to crush them to a fine powder and solubilize them in liquid before administration. In addition, tubes should be flushed with water before and after the administration of any medications.

Several maneuvers are useful for clearing a clogged feeding tube. The tube can be irrigated with warm saline, a carbonated liquid, cranberry juice, or a pancreatic enzyme solution (e.g., Viokase). Commonly, a mixture of lipase, amylase, and protease (Pancrease) dissolved in sodium bicarbonate solution (for enzyme activation) is instilled into the tube with a syringe and the tube clamped for approximately 30 minutes to allow enzymatic degradation of precipitated enteral feedings. The tube is then vigorously flushed with saline. The pancreatic enzyme solution was successful in restoring tube patency in 96% of cases where formula clotting was the likely cause of occlusion and use of cola or water had failed [36,37]. Prevention of tube clogging with flushes and pancreatic enzyme are, therefore, the methods of choice in maintenance of chronic enteral feeding tubes.

Utility of Ultrasonography for Feeding Tube Insertion

Ultrasonography has useful application related to insertion of a feeding tube.

The insertion of a gastric tube may be facilitated with ultrasonography by identifying the nasogastric tube in the upper esophagus and confirming its placement in the stomach by direct visualization (Video 21.1) [38,39]. The tube may also be guided into a postpyloric position using real-time ultrasonography guidance (Video 21.1) [40,41]. For this application when compared to blind insertion technique,
ultrasonography guidance has a higher success rate, takes less time, and reduces the need for postprocedure radiograph. Being a straightforward bedside technique, it has advantage over fluoroscopic, endoscopic, or electromagnetic guidance of postpyloric tube placement, given the simplicity of ultrasonography. The main disadvantage to ultrasonography guidance is that abdominal wounds and dressings can prevent its use, and patient specific factors such as obesity or intestinal gas may block visualization of the tube as it passes into the duodenum or the jejunum.
REFERENCES

Gastroesophageal variceal hemorrhage is an acute and catastrophic condition that occurs in one-third to one-half of patients with portal pressures greater than 12 mm Hg or a portal–IVC pressure gradient of ≥5 mm Hg [1]. Because proximal gastric varices and varices in the distal 5 cm of the esophagus lie in the superficial lamina propria, they are more likely to bleed and respond to endoscopic treatment [2]. Variceal rupture may be predicted by Child–Pugh class, red wale markings indicating epithelial thickness, and variceal size [1]. Although urgent endoscopy, sclerotherapy, and band ligations are considered first-line treatments, balloon tamponade remains a valuable intervention for the treatment of bleeding esophageal varices. Balloon tamponade is accomplished using a multilumen tube, approximately 1 m in length, with esophageal and gastric cuffs that can be inflated to compress esophageal varices and gastric submucosal veins, thereby providing hemostasis through tamponade, while incorporating aspiration ports for diagnostic and therapeutic usage.

HISTORICAL DEVELOPMENT

In 1930, Westphal described the use of an esophageal sound as a means of controlling variceal hemorrhage. In 1947, successful control of hemorrhage by balloon tamponade was achieved by attaching an inflatable latex bag to the end of a Miller–Abbot tube. In 1949, a two-balloon tube was described by Patton and Johnson. A triple-lumen tube with gastric and esophageal balloons, as well as a port for gastric aspiration, was described by Sengstaken and Blakemore in 1950. In 1955,
Linton and Nachlas engineered a tube with a larger gastric balloon capable of compressing the submucosal veins in the cardia, thereby minimizing flow to the esophageal veins, with suction ports above and below the balloon. The Minnesota tube was described in 1968 as a modification of the Sengstaken–Blakemore tube, incorporating the esophageal suction port, which is described later. Several studies have published combined experience with tubes such as the Linton–Nachlas tube; however, the techniques described here are limited to the use of the Minnesota and Sengstaken–Blakemore tubes.
ROLE OF BALLOON TAMPODaemon FOR THE MANAGEMENT OF BLEEDING ESOPHAGEAL VARICES

Treatment of portal hypertension to prevent variceal rupture includes primary and secondary prophylaxis. Primary prophylaxis consists of β-blockers, band ligation, and endoscopic surveillance, whereas secondary prophylaxis includes nitrates, transjugular intrahepatic portosystemic shunt (TIPS), and surgical shunts [3]. Management of acute variceal bleeding involves multiple simultaneous and sequential modalities. Balloon tamponade is considered a temporary bridge within these modalities. Self-expanding metal stents as an alternative to balloon tamponade are promising and currently under investigation [4,5].

Splanchnic vasoconstrictors such as somatostatin; octreotide; terlipressin (the only agent shown to decrease mortality); or vasopressin (with nitrates to reduce cardiac side effects) decrease portal blood flow and pressure, and should be administered as soon as possible [6–8]. In fact, Pourriot et al. [9] advocate administration of octreotide by emergency medical personnel before patient transfer to the hospital. Emergent therapeutic endoscopy in conjunction with pharmacotherapy is more effective than pharmacotherapy alone and is also performed as soon as possible. Band ligation has a lower rate of rebleeding and complications when compared with sclerotherapy, and should be performed preferentially, provided that visualization is adequate to ligate or scleroze varices successfully [3,10]. Tissue adhesives such as polidocanol and cyanoacrylate delivered through an endoscope are being used and studied outside the United States though glue embolization remains a concern [5].

Balloon tamponade is performed to control massive variceal hemorrhage, with the hope that band ligation or sclerotherapy and secondary prophylaxis will then be possible (Fig. 22.1). If bleeding continues beyond these measures, TIPS [11] is considered. Shunt surgery [12] may be considered when TIPS is contraindicated. Other alternatives include percutaneous transhepatic embolization; emergent esophageal transection with stapling [13]; esophagogastroic devascularization with esophageal transection and splenectomy; and hepatic transplantation.
When gastric varices are noted, therapeutic options include endoscopic administration of the tissue adhesive cyanoacrylate; TIPS; balloon-occluded retrograde transvenous obliteration [14]; balloon-occluded endoscopic injection therapy [15]; and devascularization with splenectomy, shunt surgery, or liver transplantation.

**FIGURE 22.1** Management of esophageal variceal hemorrhage. Dx, diagnosis; Rx, therapy; TIPS, transjugular intrahepatic portosystemic shunt.
INDICATIONS AND CONTRAINDICATIONS

A Minnesota or Sengstaken–Blakemore tube is indicated for patients with a diagnosis of esophageal variceal hemorrhage, in which neither band ligation nor sclerotherapy is technically possible, readily available, or has failed [16]. If at all possible, making an adequate anatomic diagnosis is critical before any of these balloon tubes are inserted. Severe upper gastrointestinal bleeding attributed to esophageal varices in patients with clinical evidence of chronic liver disease results from other causes in up to 40% of cases. The observation of a white nipple sign (platelet plug) during endoscopy is indicative of a recent variceal bleed. A balloon tube is contraindicated for patients with recent esophageal surgery or esophageal stricture [17]. Some authors do not recommend balloon tamponade when a hiatal hernia is present, but there are reports of successful hemorrhage control in some of these patients [18]. When there are no other options, it may be practical to titrate to the lowest effective balloon pressures especially when repeated endoscopic sclerotherapy has been performed, because there is increased risk of esophageal perforation [19].
Airway Control

Endotracheal intubation (see Chapter 8) is imperative in patients with upper gastrointestinal bleeding and hemodynamic compromise; encephalopathy; or both. The incidence of aspiration pneumonia is directly related to the presence of impaired mental status [20]. Suctioning of pulmonary secretions and blood that accumulates in the hypopharynx is facilitated in patients who have been intubated. Sedatives and analgesics are more readily administered to intubated patients, and may be required when balloon tamponade is poorly tolerated, because retching or vomiting may lead to esophageal rupture [21]. The incidence of pulmonary complications is significantly lower when endotracheal intubation is routinely used [22].

Hypovolemia, Shock, and Coagulopathy

Adequate intravenous access should be obtained with large-bore venous catheters for blood product administration and fluid resuscitation with crystalloids and colloids. Packed red blood cells should be administered keeping four to six units available in case of severe recurrent bleeding, which commonly occurs among these patients. Coagulopathies, thrombocytopenia, or qualitative platelet disorders should be treated emergently. Octreotide and other vasoconstrictive therapies should be initiated as indicated.

Clots and Gastric Decompression

If time permits, placement of an Ewald tube and aggressive lavage and suctioning of the stomach and duodenum facilitates endoscopy, diminishes the risk of aspiration, and may help control hemorrhage from causes other than esophageal varices. It should be removed prior to balloon tamponade.

Infection, Ulceration, and Encephalopathy

Mortality is increased when infection is present in bleeding cirrhotic patients. The rate of early rebleeding is also increased in the presence of infection [23]. Prophylactic antibiotic use reduces the incidence of early
rebleeding and increases survival [24]. Intravenous proton pump inhibitors are more efficacious than histamine-2-receptor antagonists for maintaining gastric pH at a goal of 7 or greater. Ulcers can form from sclerotherapy, banding, or direct cuff pressure during balloon tamponade. Shaheen et al. [25] found that the postbanding ulcers for patients receiving a proton pump inhibitor were two times smaller than those of patients who had not received a proton pump inhibitor. Rifaximin, lactulose, or lactitol may be useful, because blood and ammonia-forming bacteria in the gastrointestinal tract may contribute to encephalopathy.

**Balloons, Ports, and Preparation**

All lumens should be flushed to assure patency and the balloons inflated underwater to check for leaks. Two clean 100-mL (or larger) Foley-tip syringes and two to four rubber-shod hemostats should be readied for inflation of the balloons. To ensure that the gastric balloon will not be positioned in the esophagus, preinsertion compliance should be tested by placing 100-mL aliquots of air up to the listed maximum recommended volumes into the gastric inflation port while recording the corresponding pressures using a manometer attached to the gastric pressure port. In this way, postinsertion pressures can be compared. A portable handheld manometer allows for simpler continuous monitoring as well as patient transport and repositioning. When possible, a second manometer should be attached to the esophageal pressure port to facilitate inflation and continuous monitoring. Place a plug or hemostat on the other arm of the esophageal inflation port instead of a 100-mL syringe, because the manometer may also be used for inflation, rendering the syringe superfluous [26,27]. Both balloons are then completely deflated using suction and clamped with rubber hemostats or plugged before lubrication. The Minnesota tube (Fig. 22.2) includes a fourth lumen that allows for suctioning above the esophageal balloon [18], whereas the Sengstaken–Blakemore tube (Fig. 22.3) must have a 14 to 18 French nasogastric tube secured a few centimeters proximal to the esophageal balloon to be used for esophageal decompression. The nasogastric tube should be used even when the esophageal balloon is not inflated because inflation of the gastric balloon precludes proper drainage of esophageal secretions [28]. When the patient is to be placed in an aircraft (i.e., for evacuation), water should be instilled into balloon(s) instead of air [29].
Insertion and Placement of the Tube

The head of the bed should be elevated to reduce the risk of aspiration. Oral suction should be readied and the correct length of the tube to reach the patient’s stomach should be selected (usually 45 to 60 cm orally). If the patient is not intubated, head down with left lateral positioning should be attained to minimize the risk of aspiration [17]. When using a Minnesota tube, the esophageal aspiration port should be set to continuous suction and the tube generously lubricated with lidocaine jelly prior to inserting it through the nose or mouth into the stomach. However, the nasal route is not recommended for patients with coagulopathy or thrombocytopenia. When insertion is difficult, the tube
may be placed endoscopically [30] or with a guidewire [31]. Duarte described a technique of placing the tube in a longitudinally split Ewald tube [32]. Auscultation in the epigastrium while air is injected through the gastric lumen verifies the position of the tube, but the position of the gastric balloon must be confirmed at this time radiologically or by ultrasound if it is more expedient [33], because high placement can lead to esophageal rupture and low placement to duodenal rupture [34]. The manometer is then connected to the gastric pressure port and the gastric balloon is inflated with no more than 80 mL of air. A pressure of greater than 15 mm Hg at this stage suggests esophageal placement [27,35]. A (portable) radiograph or ultrasound must be obtained that includes the upper abdomen and lower chest (Figs. 22.4 and 22.5). When it is documented that the gastric balloon is below the diaphragm, it should be further inflated with air in 100 mL aliquots to a volume of 250 to 300 mL. The gastric balloon of the Minnesota tube can be inflated to 450 to 500 mL. If the change of manometric pressure for an aliquot is more than 15 mm Hg of the preinsertion pressure or if the gastric balloon is underinflated causing upward migration, erroneous esophageal placement should be considered. Record tube insertion depth (i.e., at the teeth). Tube balloon inlets should be clamped with rubber-shod hemostats after insufflation. Hemorrhage is frequently controlled with insufflation of the gastric balloon alone without applying traction, but for patients with torrential hemorrhage, it is necessary to apply traction (vide infra). If the bleeding continues, the manometer attached to the esophageal pressure port is used to inflate the esophageal balloon to a pressure of approximately 45 mm Hg. Some authors inflate the esophageal balloon for all patients immediately after insertion. When there is still bleeding, deflate the esophageal balloon, apply more traction, and reinflate in the event that it is a gastric variceal bleed. Pressures should be monitored and maintained.
FIGURE 22.4 Proper positioning of the Minnesota tube.
Although a confirmatory radiograph is still warranted to document the final position of the inflated gastric balloon, an advantage to ultrasonography is that it can be used real time during insertion at the bedside of the patient [33,36]. The examiner uses the phased array probe in abdominal preset to locate the stomach. This may require several different tomographic views over the anterior and lateral upper quadrant. Frequently, the stomach is easy to locate because it is often filled with blood. The tube is visualized as a linear echogenic structure within the stomach. If the tube is not easily visible, injection of 50 mL of air into the gastric lumen of the tube will yield a characteristic pattern of air bubbles within the stomach. Once the tube is confirmed to be within the stomach, the operator slowly injects air into the gastric balloon. The inflated gastric balloon is visualized as a distinct structure within the stomach that has an
echogenic curvilinear surface and that generates a strong acoustic shadow (Chapter 22 Video 22.1). The balloon enlarges in size within the stomach as inflation continues. The properly positioned gastric balloon is subdiaphragmatic in position.

Fixation and Traction Techniques

Fixation of the tube, and traction on the tube depend on the route of insertion. When the nasal route is used, attachment of a sponge rubber cuff around the tube at the nostril prevents skin and cartilage necrosis. When traction is required, the tube should be attached to a cord that is passed over a catcher’s mask for maximum transportability [37] or a pulley in a bed with an overhead orthopedic frame and aligned directly as it comes out of the nose to avoid contact with the nostril. This type of system allows maintenance of traction with a known weight of 500 to 1,500 g either temporarily with IV fluid bags [17] or more permanently with block weights. When the tube is inserted through the mouth, traction is better applied by placing a football or hockey helmet on the patient and attaching the tube to the face mask of the helmet after a similar weight is applied for tension. Pressure sores can occur on the head and forehead if the helmet does not fit properly or if it is used for a prolonged period. Several authors recommend overhead traction for either oral or nasal insertion [38].

Maintenance, Monitoring, and Care

Periodically flush ports to ensure patency. To reduce encephalopathy, the gastric aspiration port should be used to thoroughly lavage the stomach before being set to low intermittent suction. It may be used later for medication administration. The esophageal port may be set to intermittent or continuous suction, depending on the extent of bleeding and drainage [35]. Tautness and inflation should be checked often and at least 1 hour after insertion, allowing for only transient fluctuations of as much as 30 mm Hg with respirations and esophageal spasm. Sedation or a pressure decrease may be necessary if large pressure fluctuations persist. If repositioning of the tube is required, assure that the esophageal balloon is deflated. Upper limb restraints should also be in use and the head of the bed elevated. The tube is left in place a minimum of 24 hours with gastric balloon tamponade maintained continuously for up to 48 hours. The esophageal balloon should be deflated for 5 minutes every 6 hours to help prevent mucosal ischemia and esophageal necrosis.
Radiographic assurance of correct placement should be obtained every 24 hours and when dislodgement is suspected (Fig. 22.5). Watch for localized cervical edema, which may signal obstruction or malpositioning [39]. A pair of scissors should be kept with the apparatus in case rapid decompression becomes necessary, because balloon migration can acutely obstruct the airway or rupture the esophagus. It is advisable to take care not to utilize bare hemostats and to clamp at the thicker portion of the ports, because it is possible for the lumen to become obliterated and the tube thus impacted [40].

**Removal of the Tube**

Once hemorrhage is controlled, the esophageal balloon is deflated first. This may be done incrementally over time if desired. The gastric balloon is left inflated for an additional 24 to 48 hours and may be deflated when there is no evidence of bleeding. The tube is left in place 24 hours longer. If bleeding recurs, the balloon is reinflated. The tube is removed if no further bleeding occurs. Primary therapy and secondary prophylaxis, as described previously, should be considered because balloon tamponade is a bridge intervention and rebleeding occurs in up to two-thirds of patients within 3 months without therapy [3].
COMPLICATIONS

Rebleeding when the cuff(s) is deflated should be anticipated. The highest risk of rebleeding is in the first few days after balloon deflation. By 6 weeks, the risk of rebleeding returns to the premorbid risk level. Independent predictors of mortality of patients undergoing balloon tamponade, described by Lee et al. [41], include blood transfusion greater than 10 units; coagulopathy; presence of shock; abnormal Glasgow Coma Score; and high total volume of sclerosing agent (ethanolamine).

Aspiration pneumonia is the most common complication of balloon tamponade with incidence ranging from 0% to 12%. Acute laryngeal obstruction and tracheal rupture are the most severe of all complications, and the worst examples of tube migration or malpositioning. Migration of the tube occurs when the gastric balloon is not inflated properly after adequate positioning in the stomach or when excessive traction (>1.5 kg) is used, causing migration cephalad to the esophagus or hypopharynx. Mucosal ulceration of the gastroesophageal junction is common and is directly related to prolonged traction times (>36 hours). Perforation of the esophagus has been reported as a result of misplacing the gastric balloon above the diaphragm (Fig. 22.6). The incidence of complications that are a direct cause of death ranges from 0% to 20%.

ABDOMINAL PARACENTESIS

Indications

Abdominal paracentesis is a simple procedure that can be easily performed at the bedside in the intensive care unit and may provide important diagnostic information or therapy for critically ill patients with ascites. As a diagnostic intervention, abdominal paracentesis with removal of 20 mL of peritoneal fluid is performed to determine the etiology of the ascites or to ascertain whether infection is present, as in spontaneous bacterial peritonitis [1]. It can also be used in any clinical situation in which the analysis of a sample of peritoneal fluid might be useful in ascertaining a diagnosis or guiding therapy. The evaluation of ascites should therefore include ascitic fluid analysis.

As a therapeutic intervention, abdominal paracentesis is usually performed to drain large volumes of abdominal ascites, termed large-volume paracentesis (LVP), sometimes with removal of more than 5 L of ascitic fluid [2]. Ascites is the most common presentation of decompensated cirrhosis, and its development heralds a poor prognosis, with a 50% 2-year survival rate. Effective first-line therapy for ascites includes sodium restriction (2 g per day), use of diuretics, and LVP. When tense or refractory ascites is present, LVP is safe and effective, and has the advantage of producing immediate relief from ascites and its associated symptoms [3]. LVP can be palliative by diminishing abdominal pain from distention or relieving respiratory symptoms by allowing better diaphragmatic excursion in patients who have ascites refractory to aggressive medical management.

Refractory ascites occurs in 10% of patients with cirrhosis and is
associated with substantial morbidity and a 1-year survival of less than 50% [4,5]. For patients with refractory ascites, transjugular intrahepatic portosystemic shunt (TIPS) is superior to LVP for long-term control of ascites, but it is associated with greater encephalopathy risk and does not affect mortality [6,7].

Techniques

Before abdominal paracentesis is initiated, a catheter may be inserted to drain the urinary bladder, and correction of any underlying coagulopathy or thrombocytopenia should be considered. A consensus statement from the International Ascites Club states that “there are no data to support the correction of mild coagulopathy with blood products prior to therapeutic paracentesis, but caution is needed when severe thrombocytopenia is present” [3]. The practice guideline from the American Association for the Study of Liver Diseases (AASLD) states that routine correction of prolonged prothrombin time or thrombocytopenia is not required when experienced personnel perform paracentesis [2]. This has been confirmed in a study of 1,100 LVPs in 628 patients [8]. But in critically ill patients, there is still uncertainty as to the optimal platelet count and prothrombin time for the safe conduct of paracentesis.

The patient must next be positioned correctly. In critically ill patients, the procedure is performed in the supine position with the head of the bed elevated at 30 to 45 degrees. If the patient is clinically stable and therapeutic LVP is being performed, the patient can be placed in the sitting position, leaning slightly forward, to increase the total volume of ascites removed.

The site for paracentesis on the anterior abdominal wall is then chosen (Fig. 23.1). The preferred site is in the lower abdomen, lateral to the rectus abdominis muscle and inferior to the umbilicus. It is important to stay lateral to the rectus abdominis muscle to avoid injury to the inferior epigastric artery and vein. In patients with chronic cirrhosis and caput medusae (engorged anterior abdominal wall veins), these visible vascular structures must be avoided. Injury to these veins can cause significant bleeding because of the underlying portal hypertension and may result in hemoperitoneum. The left lower quadrant of the abdominal wall is preferred over the right lower quadrant for abdominal paracentesis because critically ill patients often have cecal distention. The ideal site is therefore in the left lower quadrant of the abdomen, lateral to the rectus abdominis muscle in the midclavicular line and inferior to the umbilicus. It has also been determined that the left lower quadrant is significantly thinner and the depth of ascites greater compared with the infraumbilical midline position, confirming the left lower quadrant as the preferred location for paracentesis [9].
If the patient had previous abdominal surgery limited to the lower abdomen, it may be difficult to perform a paracentesis in the lower abdomen and ultrasonic guidance is recommended for site selection. The point of entry, however, remains lateral to the rectus abdominis muscle in the midclavicular line. If there is concern that the ascites is loculated because of a previous abdominal surgery or peritonitis, abdominal paracentesis should be performed under ultrasound guidance to prevent iatrogenic complications.

Abdominal paracentesis can be performed by the needle technique, by the catheter technique, or with ultrasound guidance. Diagnostic paracentesis usually requires 20 to 50 mL peritoneal fluid and is commonly performed using the needle technique. However, if large volumes of peritoneal fluid are required, the catheter technique is used, because it is associated with a lower incidence of complications. LVP should always be performed with the catheter technique. Ultrasound guidance is recommended because it can be helpful both in diagnostic paracentesis using the needle technique and in LVP using the catheter technique.

Utility of Ultrasonography for Guidance of Paracentesis
Compared to standard landmark technique, guidance of paracentesis with ultrasonography is associated with a higher success rate and lower complication rate [10,11].

**Identification of Ascites.** Intra-abdominal fluid is readily identified with ultrasonography. In small amounts, it is identified in the hepatorenal recess, the splenorenal recess, and the pelvic area (Chapter 23 Video 23.1). In larger amounts, it accumulates in the prehepatic space, the presplenic space, the subphrenic area, in the pelvis; and the flanks bilaterally (Chapter 23 Video 23.2). Air-filled bowel will float on the ascitic fluid; so characteristically, ultrasonography examination of the anterior abdomen detects air artifact with the fluid distributing in dependent position.

**Characterization of Ascites.** Intra-abdominal fluid may have a variety of appearances. Uncomplicated ascites, as occurs with heart failure or portal hypertension, is typically anechoic (Chapter 23 Video 23.3). Purulent ascites is more echoic and may be septated (Chapter 23 Video 23.4). Malignant ascites in the peritoneal compartment may have a variety of complex patterns (Chapter 23 Video 23.5). Air bubbles appear as small hyperechoic mobile elements within the ascites (Chapter 23 Video 23.6). Hemoperitoneum, if very recent, has a homogenous echoic pattern (Chapter 23 Video 23.7). In the absence of patient movement, the red blood cells sediment by gravitational effect to result in a distinct interface between the hypoechoic-dependent cellular collection and the anechoic-nondependent plasma. The interface may be distinct and linear in appearance. Purulent ascites may also result in this pattern. The finding of an interface has implications regarding the cell count of in the fluid when it is sampled with paracentesis. If the sample is drawn from the anechoic fluid area, the cell count will be low when compared to a sample drawn from the dependent area. Patient movement will result in mixing of the two compartments, with a more representative cell count of the paracentesis sample. The finding of a sedimentation interface with clinical risk of hemoperitoneum immediately alerts the intensivist to the possibility of major blood loss into the peritoneal compartment.

**Guidance of Paracentesis**

**Equipment.** The ultrasonography examination is performed using a phased-array cardiac probe with abdominal preset or a standard curved array abdominal probe, if available. The linear high frequency probe lacks sufficient penetration to visualize deeper abdominal structures such as
bowel, but is useful for examining the planned needle trajectory for vascular structures that would contraindicate device insertion.

**Scanning technique.** The lower lateral abdominal quadrant areas are the preferred site for paracentesis with the suprapubic approach as an alternative. A series of scan lines are performed over the flank areas in order to identify and characterize the ascites; and to establish a safe site for needle insertion that avoids injury to adjacent organs. The critically ill patient is generally in supine position, unlike thoracentesis; this is usually not a problem for paracentesis. Occasionally, the patient will need to be rolled into an ipsilateral decubitus position in order to distribute the fluid into a better target position.

**Identification of fluid.** The examiner seeks three characteristic findings that are typical for ascites.

- An anechoic or relatively hypoechoic space that is surrounded by typical anatomic boundaries. This space represents the ascites.

- Typical anatomic boundaries: This requires unequivocal identification of bowel structures, the liver, or the spleen.

- Dynamic changes: This requires identification of dynamic changes that are typical of ascites such as movement of bowel within the fluid and shape change of the ascitic fluid with forward force application of the probe against the abdominal wall (Chapter 23 Video 23.8). This characteristic of shape change of the ascites does not occur with pleural fluid, because forward force application of the probe against the rigid chest wall does not alter the shape of the pleural effusion.

**Site selection.** The transducer is moved over the target area, in order to identify a safe site for needle insertion that maximizes the distance between the abdominal wall and underlying bowel and anatomic structures such as the liver or spleen. As much as possible, the examiner holds the probe perpendicular to the abdominal wall, because this angle is easiest to duplicate with the needle–syringe assembly. Once a suitable site is identified, it is marked; the depth of needle penetration to access the fluid is measured; and the angle of the probe is determined. This angle will be duplicated by the operator during needle insertion. It is best avoid a needle trajectory that is adjacent to the liver or spleen.

A rare complication of paracentesis is laceration of an abdominal blood wall vessel with subsequent hemoperitoneum. This risk may be reduced by using the high frequency vascular probe to scan the proposed needle trajectory. Using color Doppler, identification of a vessel may allow the operator to select an alternative site.
**Performance of needle insertion.** Once the site is selected, there can be no further patient movement, because this may shift the position of the ascites relative to the insertion site. The time between the ultrasonography examination and needle insertion is minimized. Immediately before the sterile preparation, the operator rechecks the site, angle, and depth for needle insertion. The paracentesis is performed with free-hand technique by inserting the needle–syringe assembly at the site mark, duplicating the angle at which the probe was held to determine a safe trajectory. Real-time guidance of needle insertion is not required for safe paracentesis.

**Pitfalls of imaging**

- **Skin compression:** In the edematous or obese patient, skin compression artifact may cause an under estimation of the depth for successful needle insertion. In this case, the operator pushes the probe into the skin surface in order to improve image quality causing indentation of the skin at the target site that rebounds when the probe is removed. This results in a underestimation of the depth required for the needle to access the fluid. This is problematic at the time of needle insertion, because the operator must insert the needle to a depth greater than measured with indentation of the skin.

- **Site mark movement:** If lateral force is applied to the skin at the time of marking the insertion site, the skin mark may be moved to a substantial extent. This is of special concern when accessing a smaller amount of ascites. At the time of needle insertion, the operator takes care to not move the mark site when applying pressure to the skin surface.

- **Difficult scanning conditions:** It may be difficult to achieve adequate image quality in the obese or edematous patient.

- **Aberrant position of vascular structure:** The epigastric artery is ordinarily positioned at the lateral border of the rectus muscle, so it is well away from the usual site of paracentesis which is lower in the flank area. However, the vessel may have an aberrant position, and dilated veins associated with portal hypertension may be positioned in the path of needle insertion [12]. Injury of an aberrant vessel may result in severe bleeding into the peritoneal cavity or formation of a pseudoaneurysm [13–15]. Hiroshi et al. have proposed examination of the needle trajectory before needle insertion using the high frequency vascular probe [16]. If a vessel is identified, the operator seeks an alternative site.

**Needle Technique**
With the patient in the appropriate position and the access site for paracentesis determined, the patient’s abdomen is prepared with 2% chlorhexidine gluconate and 70% isopropyl alcohol and sterile aseptic technique is used. If necessary, intravenous sedation is administered to prevent the patient from moving excessively during the procedure (see Chapter 2). After a time out, local anesthesia, using 1% or 2% lidocaine with 1:200,000 epinephrine, is infiltrated into the site. A skin wheal is created with the local anesthetic, using a short 25- or 27-gauge needle. Then, using a 22-gauge, 1.5-inch needle, the local anesthetic is infiltrated into the subcutaneous tissues and anterior abdominal wall, with the needle perpendicular to the skin. Before the anterior abdominal wall and peritoneum are infiltrated, the skin is pulled taut inferiorly, allowing the peritoneal cavity to be entered at a different location than the skin entrance site, thereby decreasing the chance of ascitic leak (Z-track technique). While tension is maintained inferiorly on the abdominal skin the needle is advanced through the abdominal wall fascia and peritoneum, and local anesthetic is injected. Intermittent aspiration identifies when the peritoneal cavity is entered, with return of ascitic fluid into the syringe. The needle is held securely in this position with the left hand, and the right hand is used to withdraw approximately 20 to 50 mL ascitic fluid into the syringe for a diagnostic paracentesis.

Once adequate fluid is withdrawn, the needle and syringe are withdrawn from the anterior abdominal wall and the paracentesis site is covered with a sterile dressing. The needle is removed from the syringe, because it may be contaminated with skin organisms. A small amount of peritoneal fluid is sent in a sterile container for Gram stain and 10 mL or quantity sufficient to achieve the fill line is inoculated into blood culture bottles immediately at bedside for culture and sensitivity. The remainder of the fluid is sent for appropriate studies, which may include cytology; cell count and differential; protein; specific gravity; amylase; pH; lactate dehydrogenase; bilirubin; triglycerides; and albumin. A serum to ascites albumin gradient (SAAG) greater than 1.1 g per dL is indicative of portal hypertension and cirrhosis (Table 23.1) [17]. Peritoneal fluid can be sent for smear and culture for acid-fast bacilli if tuberculous peritonitis is in the differential diagnosis.

| TABLE 23.1 Etiologies of Ascites Based on Normal or Diseased Peritoneum and SAAG |
|-----------------------------------------|-------------------------------|
| Normal peritoneum                      |
Portal hypertension (SAAG >1.1 g/dL)

Hepatic congestion
- Congestive heart failure
- Constrictive pericarditis
- Tricuspid insufficiency
- Budd–Chiari syndrome

Liver disease
- Cirrhosis
- Alcoholic hepatitis
- Fulminant hepatic failure
- Massive hepatic metastases

Hypoalbuminemia (SAAG < 1.1 g/dL)
- Nephrotic syndrome
- Protein-losing enteropathy
- Severe malnutrition with anasarca

Miscellaneous conditions (SAAG < 1.1 g/dL)
- Chylous ascites
- Pancreatic ascites
- Bile ascites
- Nephrogenic ascites
- Urine ascites
- Ovarian disease

Diseased peritoneum infections (SAAG < 1.1 g/dL)
- Bacterial peritonitis
- Tuberculous peritonitis
- Fungal peritonitis
- HIV-associated peritonitis

Malignant conditions
- Peritoneal carcinomatosis
- Primary mesothelioma
- Pseudomyxoma peritonei
- Hepatocellular carcinoma
Other rare conditions

- Familial Mediterranean fever
- Vasculitis
- Granulomatous peritonitis
- Eosinophilic peritonitis

SAAG, serum to ascites albumin gradient; HIV, human immunodeficiency virus.

Catheter Technique

Positioning; use of aseptic technique; and local anesthetic infiltration are the same as for the needle technique. A 22-gauge, 1.5-inch needle attached to a 10-mL syringe is used to document the free return of peritoneal fluid into the syringe at the chosen site. This needle is removed from the peritoneal cavity and a catheter-over-needle assembly is used to gain access to the peritoneal cavity. If the anterior abdominal wall is thin, an 18- or 20-gauge Angiocath can be used as the catheter-over-needle assembly. If the anterior abdominal wall is quite thick, as in obese patients, it may be necessary to use a long (5.25-inch, 18- or 20-gauge) catheter-over-needle assembly or a percutaneous single- or multiple-lumen central venous catheter (18- or 20-gauge) and gain access to the peritoneal cavity using the Seldinger technique.

The peritoneal cavity is entered as for the needle technique. The catheter-over-needle assembly is inserted perpendicular to the anterior abdominal wall using the Z-track technique; once peritoneal fluid returns into the syringe barrel, the catheter is advanced over the needle, the needle is removed, and a 20- or 50-mL syringe is connected to the catheter. The tip of the catheter is now in the peritoneal cavity and can be left in place until the appropriate amount of peritoneal fluid is removed. This technique, rather than the needle technique, should be used when LVP is performed, because complications (e.g., intestinal perforation) may occur if a needle is left in the peritoneal space for an extended period.

When the Seldinger technique is used in patients with a large anterior abdominal wall, access to the peritoneal cavity is initially gained with a needle or catheter-over-needle assembly. A guidewire is then inserted through the needle and an 18- or 20-gauge single- or multiple-lumen central venous catheter is threaded over the guidewire. It is very important to use the Z-track method for the catheter technique to prevent development of an ascitic leak, which may be difficult to control and may predispose the patient to peritoneal infection. If continued drainage of a peritoneal fluid collection is desired, a radiologist or qualified proceduralist can place a chronic indwelling peritoneal catheter using a
percutaneous guidewire technique. A video for the correct procedural technique for paracentesis is available for review [18].

**Complications**

The most common complications related to abdominal paracentesis are bleeding and persistent ascitic leak. Because most patients in whom ascites has developed also have some component of chronic liver disease with associated coagulopathy and thrombocytopenia, it is very important to consider correction of any underlying coagulopathy before proceeding with abdominal paracentesis. In addition, it is very important to select an avascular access site on the anterior abdominal wall. The Z-track technique is very helpful in minimizing persistent ascitic leak and should always be used. Another complication associated with abdominal paracentesis is intestinal or urinary bladder perforation, with associated peritonitis and infection. Intestinal injury is more common when the needle technique is used than when the catheter technique is used. Because the needle is free in the peritoneal cavity, iatrogenic intestinal perforation may occur if the patient moves or if intra-abdominal pressure increases with Valsalva maneuver or coughing. Urinary bladder injury is less common and underscores the importance of draining the urinary bladder with a catheter before the procedure. This injury is more common when the abdominal access site is in the suprapubic location; therefore, this access site is not recommended when direct visualization is not available. Careful adherence to proper technique of paracentesis minimizes associated complications.

In patients who have large-volume chronic abdominal ascites, such as that secondary to hepatic cirrhosis or ovarian carcinoma; transient hypotension; and paracentesis-induced circulatory dysfunction (PICD) may develop during LVP. PICD is characterized by worsening hypotension and arterial vasodilation; hyponatremia; azotemia; and an increase in plasma renin activity. Evidence is accumulating that PICD is secondary to an accentuation of established arteriolar vasodilation with multiple etiologies, including the dynamics of paracentesis (the rate of ascitic fluid extraction); release of nitric oxide from the vascular endothelium; and mechanical modifications of flow dynamics due to abdominal decompression [19].

PICD is associated with increased mortality and may be prevented with the administration of plasma expanders. It is very important to obtain reliable peripheral or central venous access in these patients so that fluid
resuscitation can be performed if PICD develops during the procedure. Systematic reviews and meta-analyses have found that albumin was associated with fewer complications of LVP (PICD, hyponatremia, and overall morbidity and mortality) compared to other treatments [20,21]. AASLD guidelines suggest that albumin (6 to 8 g per liter ascites removed) can be considered for LVP in which >5 L of ascites is removed.

Because PICD pathogenesis may be caused by accentuated splanchnic vasodilation, trials comparing terlipressin (a vasoconstrictor), midodrine, or octreotide with albumin have reported conflicting results for improving systemic and renal hemodynamics and renal function, including the prevention of PICD. Additional studies are warranted to establish their efficacy [22].

LVP is only transiently therapeutic; the underlying chronic disease induces reaccumulation of the ascites. Percutaneous placement of a tunneled catheter is a viable and safe technique to consider in patients who have symptomatic malignant ascites that require frequent therapeutic paracentesis for relief of symptoms [23]. An automated pump system for treatment of refractory ascites is undergoing investigation [24].
Before the introduction of diagnostic peritoneal lavage (DPL) by Root et al. [25] in 1965, nonoperative evaluation of the injured abdomen was limited to standard four-quadrant abdominal paracentesis. Abdominal paracentesis for the evaluation of hemoperitoneum was associated with a high false-negative rate. This clinical suspicion was confirmed by Giacobine and Siler [26] in an experimental animal model of hemoperitoneum documenting that a 500-mL blood volume in the peritoneal cavity yielded a positive paracentesis rate of only 78%. The initial study by Root et al. [25] reported 100% accuracy in the identification of hemoperitoneum using 1-L peritoneal lavage fluid. Many subsequent clinical studies confirmed these findings, with the largest series reported by Fischer et al. [27] in 1978. They reviewed 2,586 cases of DPL and reported a false-positive rate of 0.2%; false-negative rate of 1.2%; and overall accuracy of 98.5%. Following its introduction in 1965, DPL was a cornerstone in the evaluation of hemoperitoneum due to blunt and penetrating abdominal injuries. However, it is nonspecific for determination of the type or extent of organ injury.

Recent advances have led to the use of ultrasound (focused assessment with sonography in trauma [FAST]; Fig. 23.2) and rapid helical computed tomography (CT) in the emergent evaluation of abdominal trauma [28]. FAST has replaced DPL as the initial screening modality of choice for severe abdominal trauma, and FAST is now part of the Advanced Trauma Life Support course [29]. Practice management guidelines from the Eastern Association for the Surgery of Trauma recommend FAST as the initial diagnostic modality to exclude hemoperitoneum [30]. DPL remains a valuable adjunct to modern imaging techniques in early trauma assessment, particularly in hemodynamically unstable patients with initial FAST examination that is negative or equivocal and in the assessment of potential hollow visceral injury in blunt abdominal trauma [31]. Diagnostic peritoneal aspiration, without a full lavage, has also been utilized successfully in these circumstances [32].
Indications

The primary indication for DPL is evaluation of blunt abdominal trauma in patients with associated hypotension. If the initial FAST examination is positive for hemoperitoneum, surgical intervention (laparotomy) is required. If the FAST examination is negative or equivocal, DPL can be considered. If the patient is hemodynamically stable and can be transported safely, CT scan of the abdomen and pelvis is the diagnostic method of choice. If the patient is hemodynamically unstable or requires emergent surgical intervention for a craniotomy, thoracotomy, or vascular procedure, it is imperative to determine whether there is a coexisting intraperitoneal source of hemorrhage to prioritize treatment of life-threatening injuries. FAST or DPL can be used to diagnose hemoperitoneum in patients with multisystem injury, who require general anesthesia for the treatment of associated traumatic injuries.
Patients with associated thoracic or pelvic injuries should also have definitive evaluation for abdominal trauma, and DPL can be used in these individuals. DPL can also be used to evaluate for traumatic hollow viscus injury, and a cell count ratio (defined as the ratio between white blood cell (WBC) and red blood cell (RBC) count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) less than or equal to 1 has a specificity of 97% and sensitivity of 100% [33].

DPL can also be used to evaluate penetrating abdominal trauma; however, its role differs from that in blunt abdominal trauma [34]. A hemodynamically unstable patient with abdominal penetrating injuries requires no further investigation and immediate laparotomy should be undertaken. Instead, the role of DPL in the hemodynamically stable patient with penetrating abdominal injury is to identify hemoperitoneum; and hollow viscus or diaphragmatic injury. DPL has also been recommended as the initial diagnostic study in stable patients with penetrating trauma to the back and flank, defining an RBC count greater than 1,000 per μL as a positive test [35]. Implementation of this protocol decreased the total celiotomy rate from 100% to 24%, and the therapeutic celiotomy rate increased from 15% to 80%.

DPL can also serve a therapeutic role. It is very effective in rewarming patients with significant hypothermia. DPL should not be performed for patients with clear signs of significant abdominal trauma and hemoperitoneum associated with hemodynamic instability or peritonitis. These patients should undergo emergent celiotomy. Pregnancy is a relative contraindication to DPL; it may be technically difficult to perform because of the gravid uterus and is associated with a higher risk of complications. Bedside ultrasound evaluation of the abdomen in the pregnant trauma patient is associated with least risk to the woman and to the fetus. An additional relative contraindication to DPL is multiple previous abdominal surgeries due to abdominal adhesions, and difficulty in gaining access to the free peritoneal cavity. If DPL is indicated and ultrasound examination does not identify a safe pathway, it must be performed by the open technique to prevent iatrogenic complications such as intestinal injury.

**Techniques**

Three techniques can be used to perform DPL: (a) the closed percutaneous technique, (b) the semiclosed technique, and (c) the open technique. The closed percutaneous technique, introduced by Lazarus and Nelson [36] in 1979, is easy to perform, can be done rapidly, is
associated with a low complication rate, and is as accurate as the open technique. It should not be used in patients who have had previous abdominal surgery or a history of abdominal adhesions. The open technique entails the placement of the peritoneal lavage catheter into the peritoneal cavity under direct visualization. It is more time-consuming than the closed percutaneous technique. The semiclosed technique requires a smaller incision than does the open technique and uses a peritoneal lavage catheter with a metal stylet to gain entrance into the peritoneal cavity. It has become less popular, because clinicians have become more familiar and skilled with the closed technique.

The patient is placed in the supine position for all three techniques. A catheter is placed into the urinary bladder and a nasogastric tube is inserted into the stomach to prevent iatrogenic bladder or gastric injury. The nasogastric tube is placed on continuous suction for gastric decompression. The skin of the anterior abdominal wall is prepared with 2% chlorhexidine solution and steriley draped, leaving the periumbilical area exposed. Standard aseptic technique is used throughout the procedure. Local anesthesia with 1% or 2% lidocaine with 1:200,000 epinephrine is used as necessary throughout the procedure. The infraumbilical site is used unless there is clinical concern of possible pelvic fracture and retroperitoneal or pelvic hematoma, in which case the supraumbilical site is optimal.

Closed Percutaneous Technique

With the closed percutaneous technique, local anesthesia is infiltrated inferior to the umbilicus and a 5-mm skin incision is made just at the inferior umbilical edge. An 18-gauge needle is inserted through this incision and into the peritoneal cavity, angled toward the pelvis at approximately a 45-degree angle with the skin. The penetration through the linea alba and then through the peritoneum is felt as two separate “pops.” A J-tipped guidewire is passed through the needle and into the peritoneal cavity, again directing the wire toward the pelvis by maintaining the needle at a 45-degree angle to the skin. The 18-gauge needle is then removed and the DPL catheter inserted over the guidewire into the peritoneal cavity, using a twisting motion and guided inferiorly toward the pelvis. The guidewire is then removed, and a 10-mL syringe is attached to the catheter for aspiration. If free blood returns from the DPL catheter before the syringe is attached or if gross blood returns in the syringe barrel, hemoperitoneum has been documented, the catheter is removed, and the patient is quickly transported to the operating room for emergent celiotomy. If no gross blood returns on aspiration through the catheter, peritoneal lavage is performed using 1 L Ringer’s lactate solution or normal saline that has been previously warmed to prevent
hypothermia. The fluid is instilled into the peritoneal cavity through the DPL catheter; afterward, the peritoneal fluid is allowed to drain out of the peritoneal cavity by gravity until the fluid return slows. A minimum of 250 mL lavage fluid is considered a representative sample of the peritoneal fluid [37]. A sample is sent to the laboratory for determination of RBC count; WBC count; amylase concentration; and presence of bile, bacteria, or particulate matter. When the lavage is completed, the catheter is removed and a sterile dressing applied over the site. Suture approximation of the skin edges is not necessary when the closed technique is used for DPL.

Semiclosed Technique

Local anesthetic is infiltrated in the area of the planned incision and a 2- to 3-cm vertical incision made in the infraumbilical or supraumbilical area. The incision is continued sharply down through the subcutaneous tissue and linea alba, and the peritoneum is then visualized. Forceps, hemostats, or Allis clamps are used to grasp the edges of the linea alba and elevate the fascial edges to prevent injury to the underlying abdominal structures. The DPL lavage catheter with a metal inner stylet is inserted through the closed peritoneum into the peritoneal cavity at a 45-degree angle to the anterior abdominal wall, directed toward the pelvis. When the catheter–metal stylet assembly is in the peritoneal cavity, the DPL catheter is advanced into the pelvis and the metal stylet removed. A 10-mL syringe is attached to the catheter, and aspiration is conducted as previously described. When the lavage is completed, the fascia must be reapproximated with sutures, the skin closed, and a sterile dressing applied.

Open Technique

After the administration of appropriate local anesthetic, a vertical midline incision approximately 3 to 5 cm long is made. This incision is commonly made in the infraumbilical location, but in patients with presumed pelvic fractures or retroperitoneal hematomas or in pregnant patients, a supraumbilical location is preferred. The vertical midline incision is carried down through the skin, subcutaneous tissue, and linea alba under direct vision. The linea alba is grasped on either side using forceps, hemostats, or Allis clamps; and the fascia is elevated to prevent injury to the underlying abdominal structures. The peritoneum is identified, and a small vertical peritoneal incision is made to gain entrance into the
The DPL catheter is then inserted into the peritoneal cavity under direct visualization and advanced inferiorly toward the pelvis. It is inserted without the stylet or metal trocar. When in position, a 10-mL syringe is attached for aspiration. If aspiration of the peritoneal cavity is negative (i.e., no gross blood returns), peritoneal lavage is performed, as described earlier in the chapter. As in the semiclosed technique, the fascia and skin must be reapproximated to prevent dehiscence or evisceration, or both.

A prospective randomized study documented that closed percutaneous DPL can be performed faster than the open procedure (1 to 3 minutes vs. 5 to 24 minutes) [38]. The closed percutaneous technique was as accurate as the open procedure and was associated with a lower incidence of wound infections and complications. The closed percutaneous technique, using the Seldinger technique, should therefore be used initially in all patients except those who have had previous abdominal surgery or in pregnant patients. This has been confirmed in a study of 2,501 DPLs performed over a 75-month period for blunt or penetrating abdominal trauma [39]. The majority (2,409, or 96%) were performed using the closed percutaneous technique, and 92 (4%) were done open because of pelvic fractures, previous scars, or pregnancy. Open DPL was less sensitive than closed DPL in patients who sustained blunt trauma (90% vs. 95%), but slightly more sensitive in determining penetration (100% vs. 96%). Overall, there were few (21, [0.8%]) complications, and the overall sensitivity, specificity, and accuracy were 95%, 99%, and 98%, respectively, using an RBC count of 100,000 per μL in blunt trauma and 10,000 per μL in penetrating trauma as the positive threshold. A meta-analysis concluded that the closed DPL technique is comparable to the standard open DPL technique in terms of accuracy and major complications, with the advantage of reduced performance time with closed DPL, which is offset by increased technical difficulties and failures [40].

A DPL modification [41] that resulted in more rapid infusion and drainage of lavage fluid used cystoscopy irrigation tubing for instillation and drainage of the lavage fluid, saving an average of 19 minutes per patient for the DPL completion. This modification can be applied to the closed percutaneous or open DPL technique to decrease the procedure time in critically ill patients.

**Interpretation of Results**

The current guidelines for interpretation of positive and negative results of DPL are provided in Table 23.2. A positive result can be estimated by the inability to read newsprint or typewritten print through the lavage fluid as it returns through clear plastic tubing. This test is not reliable,
however, and a quantitative RBC count in a sample of the peritoneal lavage fluid must be performed [42]. For patients with nonpenetrating abdominal trauma, an RBC count greater than 100,000 per μL of lavage fluid is considered positive and requires emergent celiotomy. Fewer than 50,000 RBCs per μL is considered negative and RBC counts of 50,000 to 100,000 per μL are considered indeterminate. The guidelines for patients with penetrating abdominal trauma are much less clear with clinical studies using an RBC count of greater than 1,000 or 10,000 per μL to greater than 100,000 per μL as the criterion for a positive DPL in patients with penetrating thoracic or abdominal trauma. The lower the threshold, the more sensitive the test, but the higher the nontherapeutic laparotomy rate.

NEGATIVE

Nonpenetrating abdominal trauma

- RBC count <50,000/μL
- WBC count <100/μL
- Cell count ratio (defined as the ratio between WBC and RBC count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) <1
- Amylase <75 U/100 mL

Penetrating abdominal trauma

- RBC count used is variable, from <1,000/μL to <50,000/μL
- WBC count <100/μL
- Amylase <75 U/100 mL

RBC, red blood cell; WBC, white blood cell.

Determination of hollow viscus injury by DPL is much more difficult. A WBC count greater than 500 per μL of lavage fluid or an amylase concentration greater than 175 units per dL of lavage fluid is usually considered positive. These studies, however, are not as accurate as the use of RBC count in the lavage fluid to determine the presence of hemoperitoneum. One study in patients with blunt abdominal trauma determined that the WBC count in lavage fluid has a positive predictive value of only 23% and probably should not be used as an indicator of a positive DPL [43]. Other studies analyzed alkaline phosphatase levels in DPL fluid to determine if this assay is helpful in the diagnosis of hollow viscus injuries [44,45], but the results have been variable. A prospective study used a diagnostic algorithm of initial abdominal ultrasound, followed by helical CT and subsequent DPL (if CT was suggestive of blunt bowel or mesenteric injury) using a cell count ratio (defined as the ratio between WBC and RBC count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) greater than or equal to 1 to determine the need for laparotomy in patients with blunt abdominal injuries [46]. This proposed algorithm had a high accuracy (100%) while requiring the performance of DPL in only a few (2%) patients.

p. 192

p. 193

It must be stressed that DPL is not accurate for determination of retroperitoneal visceral injuries or diaphragmatic injuries [47]. The
The incidence of false-negative DPL results is approximately 30% in patients who sustained traumatic diaphragmatic rupture. In addition, DPL is insensitive in detecting subcapsular hematomas of the spleen or liver that are contained, without hemoperitoneum.

**Complications**

Complications of DPL by the techniques described here include malposition of the lavage catheter; injury to the intra-abdominal organs or vessels; iatrogenic hemoperitoneum; wound infection or dehiscence; evisceration; and possible unnecessary laparotomy. DPL is a very valuable technique, however, and if it is performed carefully, with attention to detail, these complications are minimized. In the largest series published to date, with more than 2,500 DPLs performed, the complications rate was 0.8% [39]. Wound infection, dehiscence, and evisceration are more common with the open technique; therefore, the closed percutaneous technique is recommended in all patients who do not have a contraindication to this technique. Knowledge of all techniques is necessary, however, because the choice of technique should be based on the individual patient’s presentation.

Image-guided percutaneous drainage procedures have been established as safe and effective alternatives to surgery for the first-line treatment of clinically important fluid collections in the body. Image guidance typically provided by ultrasonography or computed tomography (CT) allows for precise localization of fluid collections and faster patient recovery times than open surgical techniques. Rapid image localization and percutaneous treatment has played a major role for avoiding the morbidity and mortality associated with surgical exploration [1–4].

GENERAL AIMS

The interventional radiologist should be part of the clinical team to help determine the clinical impact of a fluid collection and the expected outcome of percutaneous treatment. Close communication between interventional and critical care staff is, therefore, essential. Image-guided aspiration or drainage procedures can alleviate symptoms because of mass effect or infection, provide fluid samples for laboratory characterization to refine treatment, and cause reduction in sepsis [5]. A list of fluid collections amenable to image-guided procedures is provided in Table 24.1.

CT and ultrasound are the two main imaging modalities used for percutaneous image guidance. Magnetic resonance imaging (MRI)-guided drainage is available at some academic institutions, but has been limited by availability, cost, and paucity of MRI-compatible interventional devices. The choice between CT and ultrasound is ultimately determined by experienced operator, availability of equipment, and nature of the collection, such as size and location. Advantages of ultrasound include portability, lack of radiation, relatively low cost, and real-time visualization of needle placement into a collection (Fig. 24.1). Because ultrasound machines all currently have Doppler capability, arterial and venous structures along access routes to fluid are identified and avoided. Ultrasound is also not limited in its approach to a target as with CT which usually requires working in a fixed plane (axial). Limitations of ultrasound include poor visualization of deep collections secondary to large body habitus, bone, overlying bowel gas, or surgical dressings. CT, on the other hand, may provide better visualization of deep collections, such as those located in the pelvis or retroperitoneal space, and a fluid collection’s location relative to vital structures. The main limitations of CT include its lack of portability, radiation exposure, and cost. With the advent of faster parallel processors and reconstruction algorithms, CT fluoroscopy now exists that allows procedures to be performed faster and with less radiation to the patient [7,8].

B: An ultrasound image demonstrating needle placement into the distended gallbladder (arrowhead) during ultrasound-guided cholecystostomy tube placement.
INDICATIONS

The indications for image-guided drainage and aspiration include, but are not limited to, fluid sampling to assess infected versus sterile collections, and abscess drainage. Sampling of a presumed infected collection for culture and antibiotic sensitivity, even after broad-spectrum antibiotics have been started, has been found to help tailor therapy in most patients [9]. Although fluid collections regardless of whether they are infected or benign (such as a seroma, lymphocele, or cyst of the kidney or liver) may cause issues for the patient, this is rare. Specific instances do exist and should be considered for critically ill patients, such as large volume ascites or pleural effusions causing continuous ventilator dependence or mass effect causing ureteral, biliary, or venous obstruction. For the critically ill patient, catheter drainage may stabilize the patient’s condition so that a more definitive surgical procedure can be performed at a later time [10,11]. Abscess size and consistency are important determinants of the need for percutaneous drainage. Many patients with abscesses smaller than 4 cm in maximum diameter can be treated conservatively with broad-spectrum antibiotics [12]. When the interventional radiologist believes a collection represents an infected hematoma or a maturing infection, regardless of size, they may request initial conservative management and follow-up imaging to determine when catheter placement will lead to successful drainage.
CONTRAINDICATIONS

Absolute contraindications for percutaneous drainage historically have included the absence of a safe access route or uncorrectable coagulopathy, but these scenarios are now rare. A coagulopathy can usually be reversed (see Preprocedure Preparation below). Prior imaging may show a collection is inaccessible, but this is not absolute. In view of bowel motility and other options such as patient positioning, use of sterile fluid to displace structures temporarily (hydrodissection), inflation or deflation of the stomach or bladder for example, a safe route can often be found. The interventional radiologist should be able to think out of the box and offer a solution, especially in those cases where the only other alternative is surgery. For example, a transenteric (small bowel) route may allow for needle aspiration of a collection previously thought to be inaccessible [13]. If no direct route is available, the liver, kidney, and stomach may be safely transgressed during needle aspiration. Transgluteal, transvaginal, transrectal, or trans-inferior vena cava sampling provides more options for collections previously felt to be inaccessible [14–17].

When difficult to access or a coagulopathy does exist, risks and benefits have to be weighed, and this should be done in consensus with the intensive care unit (ICU) staff, and patient or health care proxy. Depending on the potential complication, the interventionalist may consider surgical backup. Patients or their health care proxy should be educated by both the clinical staff and radiologist to ensure that they are comfortable with their decision concerning a drainage procedure.
RISKS, BENEFITS, AND ALTERNATIVES

Overall complications associated with percutaneous drainage or aspiration are reported to be less than 15% [18]. These include damage to vital structures, bleeding, infection, among others. Mortality (ranging from 1% to 6%) is frequently secondary to sepsis or multiorgan failure rather than the procedure itself. Depending on the location and physical properties of an infected or a sterile collection, percutaneous drainage is curative in 75% to 90% of cases [6,18,19]. In approximately 10% of cases, percutaneous drainage can serve as a temporizing measure, allowing surgery to be postponed [12].
Regardless of the interventional procedure to be performed, certain basic principals apply to all patients. After review of the risks, benefits, and alternatives to the procedure, informed consent should be obtained from the patient or health care proxy [20]. The radiologist should have a firm understanding of the patient’s clinical status which requires a comprehensive history and physical exam. A team approach is essential. Simply ordering a procedure without direct communication of concerns and goals with the interventional radiologist is suboptimal. Each case requires image review by the interventional radiologist and a discussion with the referring physicians to determine whether additional imaging is required, the procedure is technically possible, medically warranted, or if other treatment alternatives exist.

Once a collection has been identified and determined to be clinically relevant, the access route is planned with the basic rule that it should be the shortest and least invasive path. Prior to the procedure, the patient’s primary caregivers should stop all anticoagulant medications, given that the benefits of the drainage procedure outweigh the risk to the patient from thrombosis. For example, clopidogrel (Plavix), an antiplatelet agent, should be held for 7 to 10 days before the procedure [21]. The role of a platelet transfusion just prior to a procedure in patients taking clopidogrel or other P2Y12 inhibitors is not well defined, although one unit of platelets may be prophylactically given. Rapid reversal of vitamin K agonists, such as Coumadin, can be achieved with fresh-frozen plasma and intravenous or oral vitamin K, and in extreme circumstances, a prothrombin complex concentrate. If time permits, holding Coumadin and bridging anticoagulation with low-molecular-weight heparin (given subcutaneously) or intravenous unfractionated heparin (given intravenously) [21,22] is another option. Newer target-specific anticoagulants, such as rivaroxaban and apixaban (target Factor Xa) and dabigatran (target Factor IIa), have gained traction because of predictable pharmacokinetics. A Food and Drug Administration–approved reversal agent is currently available for dabigatran, and other reversal agents for other drugs are in development [23]. It is believed that anticoagulants can be safely restarted 6 to 8 hours following the procedure. The goal is to achieve a the prothrombin time below 15 seconds, partial thromboplastin time less than 35 seconds, a platelet count greater than 50,000 per mL, and an international normalized ratio less than 1.5. However, the interventional radiologist should be flexible with these thresholds, depending on the urgency of the procedure.
The patient should have nothing to eat or drink for 4 to 6 hours prior to the study which includes tube feeds if applicable, to reduce the risk of aspiration during moderate sedation. Transient bacteremia associated with percutaneous drainage of an infected collection may require prophylactic treatment with antibiotics. The most common bacteria found in intra-abdominal abscesses are Gram-negative rods and anaerobes, particularly *Escherichia coli*, *Bacteroides fragilis*, and *Enterococcus* species. Thus, the current practice guidelines put forth by the Society of Interventional Radiology recommend the use of a third-generation cephalosporin [24]. Rarely, intravenous contrast is required to help identify a collection, so the patient’s renal function (blood urea nitrogen and creatinine) should be evaluated. If abnormal (serum creatinine > 1.5 mg per dL, GFR < 30 mL/min/1.73 m²), the patient may require hydration and pretreatment with sodium bicarbonate and oral or intravenous N-acetylcysteine (Mucomyst) [25]. For patients with a history of a prior contrast reaction, the incident should be discussed to determine whether symptoms were truly an anaphylactic reaction. In the setting of a validated contrast reaction, patients are usually pretreated with a combination of a steroid and an antihistamine. An acceptable approach is 50 mg of prednisone or 32 mg of methylprednisolone 12 hours prior to the procedure and then repeated at 2 hours prior to the procedure along with 50 mg diphenhydramine. Oral contrast may be given to patients prior to CT to better delineate bowel loops, keeping in mind the 6-hour window for nothing by mouth status to allow for sedation. Reports of unopacified bowel mistaken for an abscess collection are not uncommon.
Most image-guided drainage procedures are performed under local anesthesia in combination with moderate sedation. Typically, local anesthesia is achieved using 1% to 2% lidocaine, but longer acting agents, such as tetracaine gel or bupivacaine (lasting 4 to 8 hours), are available for procedures lasting more than a couple hours. For moderate sedation, the procedure is typically performed using a combination of intravenous fentanyl and midazolam or propofol. The interventional radiologist should be certified in the usage of conscious sedation and also be ACLS trained. Vital signs must be continuously monitored by an individual other than the radiologist and include pulse oximetry, blood pressure, and electrocardiography. For the infrequent event of cardiopulmonary resuscitation, a defibrillator, backboard, and code cart supplied with the necessary medications for advanced life support should always be available.
THERAPEUTIC CATHETER DRAINAGE

Catheter drainage systems can be introduced using the trocar or Seldinger technique. The trocar system consists of a 6.5- to 16-Fr pigtail catheter coaxially loaded over a hollow metal stiffener with a sharp inner stylet. Under image guidance, the trocar system is advanced together into the fluid collection. Next, the catheter is advanced off the cannula into the cavity, assuming its pigtail configuration. Advantages of the trocar technique include a single pass and less chance of access loss. The trocar technique is well suited to large, easily accessible collections and can be performed quickly and safely. Given the rigidity of the system, the trocar system is not recommended for drainage procedures where the collection is small or difficult to access.

An alternative to the trocar system for drain placement is the use of the Seldinger technique (Fig. 24.2). The Seldinger system involves two steps starting with insertion of an 18-gauge needle into a collection under image guidance through which a 0.035-inch guidewire is advanced into the cavity [26]. The guidewire is subsequently used for tract dilatation and catheter placement. This technique is best performed under continuous image guidance, such as CT fluoroscopy, because guidewire access can easily be lost in inexperienced hands.

FIGURE 24.2 A 65-year-old male with development of lymphocele in left pelvis following radical prostatectomy. A: Computed tomography (CT) scan obtained in supine position with overlying skin grid (arrow) allowing for precise localization of the collection (asterisk) for percutaneous needle
Catheter Selection and Fixation

Catheter lengths are fairly standardized, ranging from 20 to 35 cm in length, and make use of a locking pigtail which must be released before catheter removal. A second type of locking device, a Malecot or “mushroom” catheter, can be deployed when the abscess cavity does not contain enough room for pigtail formation. Initial catheter size is chosen based on anticipated viscosity of the fluid being drained, but catheter upsizing using the same tract is straightforward when the current size is inadequate. For large collections or deep collections that cannot be reached by a standard 35 cm catheter, the interventional radiologist may become creative and use a biliary drainage catheter or nephroureteral stent, both of which contain numerous side holes and come in longer lengths. In addition to pigtail anchorage, skin adherent locking devices are used for catheter security. In some cases (disoriented patient, prior catheter dislodgement), suturing the catheter to the skin at its entrance site may be indicated. When the time comes, the universal approach to catheter removal is to cut the catheter at the distal end closest to the hub. This will release any type of anchoring mechanism. Because a pigtail is locked using a string, this must be accounted for and may come out with the catheter or be left after removal but clearly seen emerging from the catheter entrance site. This then is removed with gentle continuous traction.

One important side note must be taken into consideration. Cholecystitis has been reported in up to 1% of critically ill patients [27], and cholecystostomy tube placement is considered first-line treatment. Because the gallbladder may be in communication with the biliary tree through ducts of Luschka, or recannalization of an occluded cystic duct can occur, the tube needs to remain in place for at least 4 weeks to create a mature tract. This ensures that upon removal, there will be no bile leakage into the peritoneal cavity. This time aspect of cholecystostomy tube placement must be considered by the clinical team and also communicated to the patient or family.

Diagnostic or Therapeutic Aspiration
Usually, a 22- or 20-gauge needle is used for simple aspiration of a fluid collection. For a hematoma or more viscous collection, 16- or 18-gauge large-bore needles can be used [2,28]. Aspirated fluid can be sent for culture, Gram stain, and cytology when indicated. Additional laboratory tests can be added, such as in the case of evaluating fluid for amylase in a peripancreatic collection or creatinine in suspected urinomas. The relevance of collections felt to be clinically important solely because of their mass effect can be tested by large volume aspiration. In general, conversion from aspiration to catheter drainage can be done easily and is usually an anticipated possibility by the interventional radiologist.
PROCEDURE

General Considerations

With the advent of portable, high-resolution ultrasound machines, some diagnostic or therapeutic procedures may be performed at the bedside, the commonest being drainage of ascites, pleural effusions, and placement of cholecystostomy tubes. A variety of size needles, guidewires, and catheters should be available to the radiologist during the procedure. Given the variation in equipment on hand and the unanticipated need for other equipment not available in an ICU, such procedures should be solely reserved for subjects who are too unstable for transport.

All procedures are done adhering to sterile technique. In principle, a unilocular collection with a well-developed cavity wall is optimal but not required for percutaneous drainage. Loculated collections can often be handled by mechanical disruption using the guidewire placed while employing the Seldinger technique for catheter placement. Some authors advocate the use of thrombolytic agents, such as tissue plasminogen activator infused through the catheter once placed to aid in breaking down loculations [29]. For multiloculated or semisolid collections unresponsive to these measures, multiple drain placements may be required. If possible, drains should be inserted into the most dependent portion of the collection and as much of the collection drained at initial placement. The clinical success of catheter placement can be related to how well the collection responds to the reduction of its volume [30]. If the collection is felt to be the result of perforation of a hollow viscous (appendicitis, diverticulitis, and perforated ulcer), or leakage from the biliary tree or urinary tract for example, then after drain placement and immediate aspiration of contents, a catheter sinogram can be performed. Gentle injection of contrast or air under CT or fluoroscopic imaging (sonogram) can identify any communication which can be invaluable when developing a treatment plan for the patient (Fig. 24.3). The chance of creating sepsis or transient bacteremia from performing a sinogram at the time of drainage is a theoretical concern but rare in practice.
**FIGURE 24.3** A 63-year-old female status post–recent sigmoid resection presenting with abdominal pain. A: Chest X-ray showing large amount of free intraperitoneal air (asterisks) concerning for bowel perforation. B: Computed tomography (CT) scan obtained with oral contrast showing large gas and fluid containing collection (arrow) from leak at the surgical anastomosis. C: CT scan performed after satisfactory position of drainage catheter into the collection. D: Owing to high drainage output (>50 mL per day), abscessogram was performed demonstrating a fistulous communication (arrow) with the descending colon.

Catheter Management

Daily rounds by the interventional radiology team should be conducted to ensure the catheter is functioning correctly. It is useful to mark the level of the skin insertion on the catheter during initial placement to allow for easy assessment of catheter dislodgement. During rounds, the skin insertion site, catheter tubing, and amount of drainage should be evaluated. Most catheters are connected to a bag for passive external drainage. If dependent catheter position in the cavity undergoing drainage is not possible, Jackson–Pratt bulb suctioning can be used.
Gentle irrigation of the abscess cavity with 10 to 20 mL of sterile saline is recommended three to four times daily to ensure patency [31]. Daily dressing changes should also be performed. In anticipation of the patient’s discharge from the hospital, the patient and his or her family should be instructed in catheter care, and visiting nursing service is arranged. The patient is advised to return to the department in the event of abdominal pain, leakage from the catheter entry site, fever, or chills. When long-term drainage is anticipated, catheters should be exchanged approximately every 3 months to avoid blockage from encrustation or debris.

**When to Remove a Catheter**

Removal of a drainage catheter too early is one of the more common causes of postprocedural morbidity and mortality. The percutaneous drainage catheter should remain in place until the volume of drainage is less than 10 mL per day for 2 consecutive days, and the patient is showing clinical improvement. Reflux around the catheter during irrigation or new pain during irrigation are also signs of complete collection response and cavity collapse. Follow-up imaging on simple collections is typically not required prior to catheter removal. Continuous high drainage (>50 mL per day) should alert the radiologist for a possible fistulous tract to bowel, pancreas, or biliary tree, and the appropriate imaging modality should be used for further evaluation [10,32] if not already performed.

**Patient Response**

Depending on the location and makeup of an infected or sterile collection, image-guided percutaneous drainage is successful in 70% to 90% of cases. Following complete evacuation of purulent material from an infected cavity, improved clinical response should be seen in a matter of hours to several days [10,13]. The parameters of improving clinical status include defervescence, reduction in pain, and resolution of leukocytosis. If there is no improvement after 2 to 3 days, suspicion should be raised for a separate, undrained collection, catheter dislodgement, or malfunction. In such cases, follow-up imaging using CT, ultrasound, or fluoroscopy with contrast injection into the collection is recommended. Semisolid collections, such as infected hematomas or pancreatic abscesses, are more resistant to drainage. In the case of a collection of necrotic debris from pancreatitis, one or more large-bore catheters (chest tubes) up to 24 Fr have been used with success, allowing a patient to avoid the morbidity of surgical debridement [33,34].
Complications

Overall complications of percutaneous drainage are reported to be less than 15% [1–4], and most are minor. Major complications (under 5%) include infection, bleeding, septicemia, injury to adjacent structures such as bowel, and death. Mortality from the procedure usually related to sepsis or organ failure, compares favorably to the surgical literature rates of 10% to 20% [35]. Inadvertent contamination of a previously sterile collection is also a possibility with prolonged catheter drainage but only occurs among approximately 1% of cases [24]. Enteric transgression can usually be treated conservatively with delayed catheter removal to allow for a mature fistulous tract to develop. Minor complications include pain, infection at the skin insertion site, transient bacteremia, and malfunction of the catheter secondary to kinking, dislodgement, or clogging with debris, such as blood clots. Pain can be minimized by judicious use of analgesics. Daily catheter evaluation by the interventional staff can serve to reduce catheter malfunction. The recurrence rate following abscess drainage has been estimated to be between 5% and 10%. Recurrence may be caused by early catheter removal, failure to completely drain a loculated collection, or fistulous communication with the bowel, pancreatic duct, or biliary system. Repeat drainage of these cavities has been shown to be successful in 50% of patients with the need for surgical drainage reduced by half [3,36].

In conclusion, image-guided percutaneous aspiration and drainage has been established as the first-line treatment for sterile or infected fluid collections in the abdomen and pelvis. Awareness of the advantages and limitations of the procedure together with an integrated management approach between interventional and critical care staff will serve to benefit the patient and improve clinical outcomes.

Percutaneous Suprapubic Cystostomy

PHILIP J. AYVAZIAN

Percutaneous suprapubic cystostomy is used to divert urine from the bladder when standard urethral catheterization is impossible or undesirable [1–9]. The procedure for placement of a small diameter catheter is rapid, safe, and easily accomplished at the bedside under local anesthesia. This chapter will first address methods for urethral catheterization before discussing the percutaneous approach.

URETHRAL CATHETERIZATION

Urethral catheterization remains the principal method for bladder drainage. The indications for the catheter should be clarified, as they influence the type and size used. A history and physical examination with particular attention to the patient’s genitourinary system is important.

Catheterization may be difficult with male patients in several instances. Patients with lower urinary tract symptoms (e.g., urinary urgency, frequency, nocturia, decreased stream, and hesitancy) may have benign prostatic hypertrophy. These patients may require a larger bore catheter, such as 20 or 22 French (Fr). Patients with a history of prior prostatic surgery such as transurethral resection of the prostate, open prostatectomy, or radical prostatectomy may have an irregular bladder neck as a result of contracture after surgery. The use of a coude tip catheter, which has an upper deflected tip, may help in negotiating the altered anatomy after prostate surgery. The presence of a high-riding prostate or blood at the urethral meatus suggests urethral trauma. In this situation, urethral integrity must be demonstrated by retrograde urethrogram before urethral catheterization is attempted.

Urethral catheterization for gross hematuria requires large catheters such as the 22 or 24 Fr, which have larger holes for irrigation and
removal of clots. Alternatively, a three-way urethral catheter may be used to provide continuous bladder irrigation to prevent clotting. Large catheters impede excretion of urethral secretions, however, and can lead to urethritis or epididymitis if used for prolonged periods.

**Technique**

In males, after the patient is prepared and draped, 10 mL of a 2% lidocaine hydrochloride jelly is injected retrograde into the urethra. Anesthesia of the urethral mucosa requires 5 to 10 minutes after occluding the urethral meatus either with a penile clamp or manually to prevent loss of the jelly. The balloon of the catheter is tested, and the catheter tip is covered with a water-soluble lubricant. After stretching the penis upward perpendicular to the body, the catheter is inserted into the urethral meatus. The catheter is advanced up to the hub to ensure its entrance into the bladder. The balloon is not inflated until urine is observed in the drainage tubing to prevent urethral trauma. Irrigation of the catheter with normal saline helps verify the position. A common site of resistance to catheter passage is the external urinary sphincter within the membranous urethra, which may contract voluntarily. Any other resistance may represent a stricture necessitating urologic consultation. In patients with prior prostate surgery, an assistant’s finger placed in the rectum may elevate the urethra and allow the catheter to pass into the bladder.

In females, short, straight catheters are preferred. Typically, a smaller amount of local anesthesia is used. Difficulties in catheter placement occur after urethral surgery, vulvectomy, vaginal atrophy, or with morbid obesity. In these cases, the meatus is not visible and may be retracted under the symphysis pubis. Blind catheter placement over a finger located in the vagina at the palpated site of the urethral meatus may be successful.

When urologic consultation is obtained, other techniques for urethral catheterization can be used. Flexible cystoscopy may be performed to ascertain the reason for difficult catheter placement and for insertion of a guidewire. A urethral catheter then can be placed over the guidewire by a Seldinger technique. Filiforms and followers are useful for urethral strictures.

**Indications**

On occasion, despite proper technique (as outlined previously), urethral catheterization is unsuccessful. These are the instances when percutaneous suprapubic cystostomy is necessary. Undoubtedly, the most common indication for percutaneous suprapubic cystostomy is for the management of acute urinary retention in men. Other indications for a
percutaneous suprapubic cystostomy in the intensive care unit are listed in Table 25.1.

Contraindications

The contraindications to percutaneous suprapubic cystostomy are listed in Table 25.2. An inability to palpate the bladder or distortion of the pelvic anatomy from previous surgery or trauma makes percutaneous entry of the bladder difficult. In these situations, the risks of penetrating the peritoneal cavity become substantial. The bladder may not be palpable if the patient is in acute renal failure with oliguria or anuria, has a small contracted neurogenic bladder, or is incontinent. When the bladder is not palpable, it can be filled in a retrograde manner with saline to distend it. In men, a 14-Fr catheter is placed in the fossa navicularis just inside the urethral meatus, and the balloon is filled with 2 to 3 mL of sterile water to occlude the urethra. Saline is injected slowly into the catheter until the bladder is palpable; then, the suprapubic tube may be placed. In patients with a contracted neurogenic bladder, it is impossible to adequately distend the bladder by this approach. For these and most patients, ultrasonography is used to locate the bladder and allow the insertion of a 22-gauge spinal needle. Saline is instilled into the bladder via the needle to distend the bladder enough for suprapubic tube placement (Fig. 25.1).

<table>
<thead>
<tr>
<th>TABLE 25.2 Contraindications to Percutaneous Cystostomy</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nonpalpable bladder</td>
</tr>
</tbody>
</table>
In patients with previous lower abdominal surgery, ultrasonographic guidance is often necessary before a percutaneous cystostomy can be performed safely. Previous surgery can lead to adhesions that can hold a loop of intestine in the area of insertion. Other relative contraindications include patients with coagulopathy, a known history of bladder tumors, or active hematuria and retained clots. In patients with bladder tumors, percutaneous bladder access should be avoided because tumor cell seeding can occur along the percutaneous tract. Suprapubic cystostomy tubes are of small caliber and therefore do not function effectively with severe hematuria and retained clots. Instead, open surgical placement of
a large caliber tube is necessary if urethral catheterization is impossible.

**Technique**

There are two general types of percutaneous cystostomy tubes that range in size from 8 to 14 Fr. The first type uses an obturator with a preloaded catheter. Examples include the Stamey catheter (Cook Urological, Spencer, IN) and the Bonanno catheter (Beckton Dickinson and Co., Franklin Lakes, NJ) [10]. The Stamey device is a polyethylene Malecot catheter with a luer lock hub that fits over a hollow needle obturator (Fig. 25.2A). When the obturator is locked to the hub of the catheter, the Malecot flanges are pulled inward (closed), and the system is ready for use. The Bonanno catheter uses a flexible 14-Fr Teflon tube, which is inserted over a hollow 18-gauge obturator (Fig. 25.2B). The obturator locks into the catheter hub and extends beyond the catheter tip. When the obturator is withdrawn, the tube pigtails in the bladder. One advantage of the Stamey catheter is that the flanges provide a secure retaining system. The Bonanno catheter generally induces fewer bladder spasms, however, and is better tolerated.

**FIGURE 25.2** A: Stamey suprapubic cystostomy trocar set (A is the obturator, B is the Malecot catheter, and C is the drainage tube). B: Bonanno catheter set (A is the obturator and B is the catheter). C: Lawrence
suprapubic catheter (A is the trocar and B is the sheath).

The second type of percutaneous cystostomy tube consists of a trocar and sheath, which are used to penetrate the abdominal wall and bladder. One of the most popular systems is the Lawrence suprapubic catheter (Rusch, Duluth, GA). This system allows a standard Foley catheter to be placed after removal of the trocar (Fig. 25.2C).

The patient is placed in the supine position; a towel roll may be placed under the hips to extend the pelvis. Trendelenburg may help to move the abdominal contents away from the bladder. The bladder is palpated to ensure that it is distended. The suprapubic region is clipped, prepared with 10% povidone-iodine solution, and draped with sterile towels. The insertion site is several centimeters above the symphysis pubis in the midline. This approach avoids the epigastric vessels. In obese patients with a large abdominal fat pad, the fold is elevated. The needle should be introduced into the suprapubic crease, where the fat thickness is minimal. After obtaining consent and performing a time-out, 1% lidocaine is used to anesthetize the skin, subcutaneous tissues, rectus fascia, and retropubic space. A 22-gauge spinal needle with a 5-mL syringe is directed vertically and advanced until urine is aspirated. If the bladder is smaller or if the patient had previous pelvic surgery, the needle is directed at a 60-degree caudal angle. Insertion of the cystostomy tube is predicated on the feasibility of bladder puncture and after the angle and depth of insertion is established with the spinal needle (Fig. 25.3).
At the site of bladder puncture, a small 2-mm incision is made with a No. 11 blade. The catheter mounted on the obturator is advanced toward the bladder. Two hands are used to grasp the system to provide a forceful, but controlled, thrust through the abdominal wall. One hand can be positioned on the obturator at a site marking the depth of the bladder. A syringe attached to the end of the obturator is used to aspirate urine and confirm obturator placement. Once the bladder is penetrated, the entire system is advanced 2 to 3 cm. This prevents the catheter tip from withdrawing into the retropubic space when the bladder decompresses. After unlocking the obturator from the catheter, the obturator acts as a guide while the catheter is advanced into the bladder. When using a
Stamey catheter, the catheter can be gently withdrawn until the Malecot flanges meet resistance against the anterior bladder wall. The Stamey catheter is then advanced 2 cm back into the bladder to allow for movement. This maneuver pulls the catheter away from the bladder trigone and helps reduce bladder spasms. The same general technique applies to placement of the Lawrence suprapubic catheter system. After the bladder is penetrated, urine appears at the hub of the suprapubic catheter introducer (trocar plus sheath). The trocar is then removed, and a Foley catheter is inserted. The Foley catheter balloon is inflated to secure it in the bladder. Pulling the tab at the top of the peel-away sheath allows the remaining portion of the sheath to be removed away from the catheter.

The patency of the catheter is assessed by irrigating the bladder after decompression. The catheter can be fixed with a simple nylon suture and sterile dressing. The Bonanno catheter contains a suture disc. The Lawrence suprapubic catheter does not require extra fixation, because the balloon on the Foley catheter secures it in place.
SUPRAPUBIC CATHETER CARE

Bladder spasms occur commonly after suprapubic catheter placement. When using a Stamey catheter or a Foley catheter, bladder spasms can be prevented by withdrawing the tube until it meets the anterior bladder wall and then advancing 2 cm back into the bladder. Persistent bladder spasms can be treated with anticholinergic therapy (e.g., oxybutynin and hyoscyamine). This medication should be discontinued before removing the suprapubic tube to prevent urinary retention.

A suprapubic tube that ceases to drain is usually caused by kinking of the catheter or displacement of the catheter tip into the retropubic space. If necessary, suprapubic catheters may be replaced using either an exchange set (available for Stamey catheters) or by dilating the cystostomy tract. Closure of the percutaneous cystostomy tract is generally prompt after the tube is removed. Prolonged suprapubic tube use can lead to a mature tract, which may take several days to close. If the tract remains open, bladder decompression via a urethral catheter may be required.
COMPLICATIONS

Placement of suprapubic cystostomy tubes is generally safe with infrequent complications. Possible complications are listed in Table 25.3. Bowel complications are severe but rare with this procedure [11,12]. Penetration of the peritoneal cavity or bowel perforation produces peritoneal or intestinal symptoms and signs. This complication can be avoided by attempting the procedure only on well-distended bladders and using a midline approach no more than 4 cm above the pubis.

In patients who have had previous lower abdominal or pelvic surgery, an ultrasound should be used to properly place the suprapubic tube and rule out entrapped bowel (Fig. 25.4).

![FIGURE 25.4](image) Placement of the suprapubic tube can perforate the entrapped bowel.
Patients who develop peritoneal symptoms and signs require a full evaluation of not only the location of the suprapubic tube (by a cystogram) but also of the cystostomy tract. A kidney-ureter-bladder X-ray and computed tomography scans may be required.

Hematuria is the most common complication after suprapublic tube placement. Rarely, it requires open cystostomy for placement of a large caliber tube for irrigation. Hematuria can occur secondary to laceration of a submucosal vessel or rapid decompression of a chemically distended bladder. It can be avoided by gradual bladder decompression.

Complications associated with the catheter include loss of a portion of the catheter in the bladder, calcification of the catheter, or bladder stone formation. These complications can be avoided by preventing prolonged catheter use. Beyond 4 weeks, evaluation and replacement or removal must be considered.

When chronically distended bladders are decompressed, patients are at risk of postobstructive diuresis. Patients who are at greatest risk include those with azotemia, peripheral edema, congestive heart failure, and mental status changes. Patients with postobstructive diuresis (i.e., urine outputs greater than 200 mL per hour) require frequent monitoring of vital signs and intravenous fluid replacement.

Hypotension rarely occurs after suprapubic tube placement. It may be caused by a vasovagal response or relief of pelvic veins compressed by bladder distention. Prompt fluid administration is the treatment for this complication.

Another rare complication is through-and-through bladder perforation. This is treated conservatively with bladder decompression.
UTILITY OF ULTRASONOGRAPHY FOR PERCUTANEOUS CYSTOSTOMY AND URETHRAL CATHETERIZATION

Ultrasonography has useful application for the performance of percutaneous cystostomy [13]. The experienced urologist will generally not use ultrasonography to perform percutaneous cystostomy; as, in their expert hands, the procedure can be performed with a high degree of safety [14]. The exception would be when there is history of lower abdominal surgery, where the risk of bowel injury is increased. It is unusual for an intensivist to perform percutaneous cystostomy, but, should the need arise, ultrasonography is particularly helpful to the less experienced operator, as the fluid-filled bladder can be readily identified with ultrasonography [7]. This allows for accurate identification of safe site, depth, and angle for device insertion into the bladder, similar in principle to that required for thoracentesis or paracentesis.

Using a transverse imaging plane, the phased array probe (or curvilinear abdominal probe if available) is placed immediately above the pubic bone in the midline. The fluid-filled bladder is identified as an anechoic space subtended by characteristic boundaries. When filled to moderate extent, the bladder has a square configuration; when distended, it becomes rounded in shape. By angling the probe from the transverse plane downward into the pelvis, the entire structure can be examined. The best site for device insertion that avoids interposed bowel is identified and marked. The risk that the bowel might be in the target area is of special concern, if there is history of lower abdominal surgery. The depth and best angle for device insertion is determined, followed by performance of the procedure. Ascites may be mistaken for a full bladder. This pitfall may be avoided by identifying bowel loops within the ascites, and by detection of ascites elsewhere in the abdomen. Ultrasonography also has useful application for the performance of difficult urethral catheterization. In the male patient with an enlarged prostate, passage of the urethral catheter may be difficult. The tip of the catheter may enter the bladder with drainage of urine, but with the catheter balloon remaining in the proximal urethra at the level of the prostate. Inflation of the balloon may injure the proximal urethra. When there is difficulty with catheter insertion and uncertainty concerning the position of the catheter balloon, real-time ultrasonography of the bladder during catheter insertion allows the intensivist to determine proper balloon position prior to its inflation. Ultrasonography guidance of catheter insertion is not
required for routine urethral catheterization.

Chapter 26

Aspiration of the Knee and Synovial Fluid Analysis

PADMANAIDU KARNAM • BONNIE J. BIDINGER • DEBORAH M. DEMARCO

Arthrocentesis is a safe and relatively simple procedure that involves the introduction of a needle into a joint space to remove synovial fluid. It constitutes an essential part of the evaluation for arthritis of unknown cause, frequently with the intent to rule out a septic process [1–3].

Ropes and Bauer [4] first categorized synovial fluid as inflammatory or noninflammatory in 1953. In 1961, Hollander et al. [5] and Gatter and McCarty [6] coined the term synovianalysis to describe the process of joint fluid analysis and were instrumental in establishing its critical role in the diagnosis of certain forms of arthritis. Septic arthritis and crystalline arthritis can be diagnosed by synovial fluid analysis alone. They may present similarly but require markedly different treatments, thus necessitating early arthrocentesis and prompt synovial fluid analysis.

INDICATIONS

Arthrocentesis is performed for diagnostic and therapeutic purposes. The main indication for arthrocentesis is to assist in the evaluation of arthritis of unknown cause. In the intensive care unit, it is most commonly performed to rule out septic arthritis or crystalline arthritis. As many types of inflammatory arthritis mimic septic arthritis, synovial fluid analysis is essential in differentiating the various causes of inflammatory arthritis [4,7] (Table 26.1). Therefore, patients presenting with acute monoarthritis or oligoarthritis require prompt arthrocentesis with subsequent synovial fluid analysis, preferably before initiation of treatment.

Arthrocentesis is also used for therapeutic purposes. In a septic joint, serial joint aspirations are often required to remove accumulated inflammatory or purulent fluid. This accomplishes complete drainage of a closed space and allows serial monitoring of the total white blood cell count, Gram stain, and culture to assess treatment response. Inflammatory fluid contains many destructive enzymes that contribute to cartilage and bony degradation; removal of the fluid may slow this destructive process \[8,9\]. Additionally, arthrocentesis allows for injection of long-acting corticosteroid preparations into the joint space, which may be a useful treatment for various inflammatory and noninflammatory forms of arthritis \[10\].

Before performing arthrocentesis, it must be ascertained that the true joint is inflamed and an effusion is present. This requires a meticulous physical examination to differentiate arthritis from periarticular inflammation. Bursitis, tendinitis, and cellulitis all may mimic arthritis. In the knee, the examination begins with assessment of swelling. A true effusion may cause bulging of the parapatellar gutters and the suprapatellar pouch \[11\]. The swelling should be confined to the joint space. To check for small effusions, the bulge test is performed \[12\]. Fluid is stroked from the medial joint line into the suprapatellar pouch and then from the suprapatellar pouch down along the lateral joint line. If a bulge of fluid is noted at the medial joint line, a small effusion is present (Fig. 26.1). If a large effusion is present, one can detect a ballotable patella by pushing it against the femur with the right index finger while applying pressure to the suprapatellar pouch with the left hand \[13\]. Comparison with the opposite joint is helpful. Many texts describe joint examination and assessment for fluid in the knee and other joints \[11–13\].

**FIGURE 26.1** The bulge test. A: Milk fluid from the
suprapatellar pouch into the joint. B: Slide the hand down the lateral aspect of the joint line and watch for a bulge medial to the joint.
CONTRAINDICATIONS

Absolute contraindications to arthrocentesis include local infection of the overlying skin or other periarticular structures and severe coagulopathy [1–3,10]. If coagulopathy is present and septic arthritis is suspected, every effort should be made to correct the coagulopathy (with fresh-frozen plasma or alternate factors; see Chapters 88 & 89 Disorders of Hemostasis) before joint aspiration. Therapeutic anticoagulation is not an absolute contraindication, but every effort should be made to avoid excessive trauma during aspiration, including using a smaller size needle. Known bacteremia is a relative contraindication because inserting a needle into the joint space disrupts capillary integrity, allowing joint space seeding [14]. However, if septic arthritis is strongly suspected, joint aspiration is indicated. The presence of articular instability (e.g., that seen with badly damaged joints) is a relative contraindication, although the presence of a large amount of presumed inflammatory fluid may still warrant joint aspiration.
COMPLICATIONS

The major complications of arthrocentesis are iatrogenically induced infection and bleeding, both of which are extremely rare [1]. The risk of infection after arthrocentesis has been estimated to be less than one in 10,000 [15]. Hollander [16] reported an incidence of less than 0.005% in 400,000 injections. Strict adherence to aseptic technique reduces the risk of postarthrocentesis infection. Significant hemorrhage is also extremely rare. Correction of prominent coagulopathy before arthrocentesis reduces this risk.

Another potential complication of arthrocentesis is direct injury to the articular cartilage by the needle. This is not quantifiable, but any injury to the cartilage could be associated with degenerative change over time. To avoid cartilaginous damage, the needle should be pushed in only as far as necessary to obtain fluid, and excessive movement of the needle during the procedure should be avoided.

Other complications include discomfort from the procedure itself, allergic reactions to the skin preparation or local anesthetic, and in the case of steroid injection, postinjection flare and local soft-tissue atrophy from the glucocorticoid [17].
TECHNIQUE

Joint aspiration is easily learned. A sound knowledge of the joint anatomy, including the bony and soft-tissue landmarks used for joint entry, is needed. Strict aseptic technique must be followed to minimize risk of infection, and relaxation of the muscles surrounding the joint should be encouraged because muscular contraction can impede the needle’s entry into the joint.

Most physicians in the intensive care unit can aspirate the knee because it is one of the most accessible joints. Other joints should probably be aspirated by an appropriate specialist, such as a rheumatologist or an orthopedic surgeon. Certain joints are quite difficult to enter blindly and are more appropriately entered using guidance with ultrasonography, fluoroscopy, or computed tomography; these include the hip, sacroiliac, and temporomandibular joints. Many texts describe in detail the aspiration technique of other joints [3,16–18]. The technique for knee aspiration is as follows:

1. Describe the procedure to the patient, including the possible complications, and obtain written informed consent.
2. Collect all items needed for the procedure (Table 26.2).
3. With the patient supine and the knee fully extended, examine the knee to confirm the presence of an effusion, as described previously.
4. Identify landmarks for needle entry. The knee may be aspirated from a medial or lateral approach. The medial approach is more commonly used and is preferred when small effusions are present. Identify the superior and inferior borders of the patella. Entry should be halfway between the borders, just inferior to the undersurface of the patella (Fig. 26.2). The entry site may be marked with pressure from the needle cover with the needle removed. An indentation mark should be visible.
5. Cleanse the area with 10% povidone-iodine or 2% chlorhexidine in 70% isopropyl alcohol (if the patient is allergic to iodine) and allow the area to dry. Practice universal precautions: wear gloves at all times while handling any body fluid, although they need not be sterile for routine knee aspiration. Do not touch the targeted area once it has been cleaned.
6. Apply local anesthesia. A local anesthetic (1% lidocaine) may be instilled subcutaneously with a 25-gauge, 1.5-in needle. Once numbing
has occurred, deeper instillation of the local anesthetic to the joint capsule can be performed. Some physicians use ethyl chloride as an alternative anesthetic. However, this agent provides only superficial anesthesia of the skin. Spray ethyl chloride directly onto the designated area and stop when the first signs of freezing are evident in order to limit potential for skin damage.

7. To enter the knee joint, use an 18- to 22-gauge, 1.5-in needle with a 20- to 60-mL syringe. Use a larger gauge needle particularly if septic arthritis is suspected as the aspirated fluid may be purulent and more difficult to aspirate. Use a quick thrust through the skin and on through the capsule to minimize pain. Avoid hitting periosteal bone, which causes significant pain, or cartilage, which causes cartilaginous damage. Aspirate fluid to fill the syringe. If the fluid appears purulent or hemorrhagic, try to tap the joint dry, which will remove mediators of inflammation that may perpetuate an inflammatory or destructive process. If the syringe is full and more fluid remains, a sterile hemostat may be used to clamp the needle, thus stabilizing it, while switching syringes. When the syringes have been switched, more fluid can be withdrawn. The syringes must be sterile.

8. On occasion, effusions can be difficult to aspirate. Reasons for this include increased fluid viscosity, fibrin and other debris impeding flow through the needle, loculated fluid, and use of a needle with an inappropriately small gauge. Additionally, the fluid may not be accessible by the approach being used [19]. At times, one can obtain a small drop of joint fluid by using continuous suction as the needle is withdrawn from the joint space [17]. This small specimen can then be sent for Gram stain, culture, and if possible, crystal analysis.

9. When fluid has been obtained, quickly remove the needle and apply pressure to the needle site with sterile gauze. When bleeding has stopped, remove the gauze, clean the area with alcohol, and apply an adhesive bandage. If the patient is receiving anticoagulation therapy or has a bleeding diathesis, apply prolonged pressure.

10. Document the amount of fluid obtained and perform a gross examination, noting the color and clarity. Send fluid for cell count with differential count, Gram stain, routine culture, specialized cultures for *Gonococcus*, *Mycobacterium*, and fungus, if indicated, and polarized microscopic examination for crystal analysis. Other tests, such as glucose and complement determinations, are generally not helpful. Use an anticoagulated tube to send fluid for cell count and crystal analysis. Sodium heparin or ethylenediaminetetraacetic acid are appropriate anticoagulants. Lithium heparin and calcium oxalate should be avoided because they can precipitate out of solution to form
crystals, thus potentially giving a false-positive assessment for crystals [6,20]. Fluid may be sent for Gram stain and culture in the syringe capped with a blunt tip or in a sterile redtop tube. It is best to check with the institution’s laboratory in advance as procedures vary regarding the handling of synovial fluid and the proper tubes in which to send it.

UTILITY OF ULTRASONOGRAPHY FOR KNEE JOINT ASPIRATION

Ultrasonography has several useful applications related to aspiration of the knee joint.

Identification of Knee Joint Effusion

Ultrasonography examination of the knee is a useful means of verifying whether there is a fluid collection in the knee joint. As indicated in this chapter, physical examination is an effective means of identifying a knee joint effusion. However, patient-specific factors such as obesity, edema, or anatomic abnormalities as well as lack of experience by the examiner may degrade the standard physical examination for knee effusion. In this case, ultrasonography is useful in identifying fluid [21]. This avoids errors that could lead to an attempt at arthrocentesis when no fluid is present or the converse, where fluid is present but not identified. The knee is examined with the leg in a straight and fully supported position. The linear vascular probe is preferred, as it has excellent resolution; and most knee joint effusions are within its depth range. The probe is placed over the medial or lateral knee joint in coronal scanning plane. The initial tomographic plane is anterior in order to identify the periosteum of the patella. The probe is moved posteriorly to move the scanning plane deep to the patella. The knee effusion is identified as an anechoic or hypoechoic space between the patella and the more posterior periosteum of the long bones of the leg. Stranding or loculations may be present suggesting a complex effusion. Other scanning planes may be utilized, but the medial or lateral approach is generally sufficient and has the added advantage that the follow through arthrocentesis is often performed at these scanning sites (Videos 26.1 and 26.2).

Guidance of Knee Aspiration

Ultrasonography may be used to guide needle insertion for aspiration of a knee effusion. Following identification of the fluid, the site is marked and, with sterile technique, the needle is inserted into the fluid collection with needle trajectory determined by the probe angle used to identify the fluid and depth for needle penetration measured from a frozen image using the
caliper function of the machine. Real-time guidance of needle insertion is not required. Ultrasonography is superior to the landmark technique in terms of patient pain, volume of fluid aspirated, and overall success rate [22]. Ultrasonography is particularly useful for the patient with difficult anatomy [23]; and for the less experienced operator who performs only an occasional knee aspiration [24]; as may hold for the intensivist.
SYNOVIAL FLUID ANALYSIS

Synovial fluid analysis is identical for all joints and begins with bedside observation of the fluid. The color, clarity, and viscosity of the fluid are characterized. Synovial fluid is divided into noninflammatory and inflammatory types on the basis of the total nucleated cell count. A white blood cell count less than or equal to 2,000 per $\mu$L indicates a noninflammatory fluid and a count greater than 2,000 per $\mu$L indicates an inflammatory fluid. Table 26.3 shows how fluid is divided into major categories on the basis of appearance and cell count.

GROSS EXAMINATION

Color

Color and clarity should be tested using a clear glass tube. Translucent plastic, as used in most disposable syringes, interferes with proper assessment [1]. Normal synovial fluid is colorless. Noninflammatory and inflammatory synovial fluids appear yellow or straw colored. Septic effusions frequently appear purulent and whitish. Depending on the number of white blood cells present, pure pus may be extracted from a septic joint. Hemorrhagic effusions appear red or brown. If the fluid looks like pure blood, the tap may have aspirated venous blood. The needle is removed, pressure is applied, and the joint is reentered from an alternate site. If the same bloody appearance is noted, the fluid is a hemorrhagic effusion and probably not related to the trauma of the aspiration. If any question remains, the hematocrit of the effusion is compared with that of peripheral blood. The hematocrit in a hemorrhagic effusion is typically lower than that of peripheral blood. In the case of a traumatic tap, the hematocrit of the fluid should be equal to that of peripheral blood. For causes of a hemorrhagic effusion, refer to Table 26.4.

Clarity

The clarity of synovial fluid depends on the number and types of cells or particles present. Clarity is tested by reading black print on a white background through a glass tube filled with the synovial fluid. If the print is easily read, the fluid is transparent. This is typical of normal and noninflammatory synovial fluid. If the black print can be distinguished from the white background, but is not clear, the fluid is translucent. This is typical of inflammatory effusions. If nothing can be seen through the
fluid, it is opaque. This occurs with grossly inflammatory, septic, and hemorrhagic fluids.

**Viscosity**

The viscosity of synovial fluid is a measure of the hyaluronic acid content. Degradative enzymes such as hyaluronidase are released in inflammatory conditions, thus destroying hyaluronic acid and other proteinaceous material, resulting in a thinner, less viscous fluid. Highly viscous fluid, on the other hand, can be seen in myxedematous or hypothyroid effusions.

Viscosity can be assessed at the bedside using the string sign [1]. A drop of fluid is allowed to fall from the end of the needle or syringe and the length of the continuous string that forms is estimated. Normal fluid typically forms at least a 6-cm continuous string. Inflammatory fluid does not form a string; instead, it drops off the end of the needle or syringe like water dropping from a faucet.
The cell count should be obtained as soon as possible after arthrocentesis, as a delay of even several hours may cause an artificially low white blood cell count [25]. The total white blood cell count of synovial fluid differentiates noninflammatory from inflammatory fluid, as noted previously. In general, the higher the total white blood cell count, the more likely the joint is to be infected. This is not absolute, however, and there is considerable overlap. For instance, a total white cell count greater than 100,000 per μL may be seen in conditions other than infection, whereas a total white blood cell count of 50,000 per μL may be due to infection, crystalline disease, or systemic inflammatory arthropathy [26].

The differential white blood cell count is also performed using the technique used for peripheral blood, typically using Wright’s stain. The differential is calculated on the basis of direct visualization. The differential count includes cells typically seen in peripheral blood, such as polymorphonuclear cells, monocytes, and lymphocytes, as well as cells localized to the synovial space. In general, the total white blood cell count and the polymorphonuclear cell count increase with inflammation and infection. Septic fluid typically has a differential of greater than 75% polymorphonuclear cells (see Table 26.3).
All fluid should be assessed for the presence of crystals. As with cell count, crystal analysis should be performed as soon as possible after arthrocentesis. A delay is associated with a decreased yield [25]. One drop of fluid is placed on a slide and covered with a coverslip; this is examined for crystals using a compensated polarized light microscope. The presence of intracellular monosodium urate (MSU) or calcium pyrophosphate dihydrate (CPPD) crystals confirms a diagnosis of gout or pseudogout, respectively. MSU crystals are typically long and needle shaped: they may appear to pierce through a white blood cell. The crystals are strongly negatively birefringent, appearing yellow when parallel to the plane of reference. Typically, CPPD crystals are small and rhomboid. The crystals are weakly positively birefringent, appearing blue when oriented parallel to the plane of reference. Rotating the stage of the microscope by 90 degrees and thereby the orientation of the crystals (now perpendicular to the plane of reference) changes their color: MSU crystals turn blue and CPPD crystals turn yellow.

In addition to MSU and CPPD crystals, other less common crystals may induce an inflammatory arthropathy. Basic calcium crystals (e.g., hydroxyapatite) and oxalate crystals are two such types. Much like MSU crystals in gout, hydroxyapatite crystals can incite acute articular and periarticular inflammation, which can be difficult to distinguish clinically from septic arthritis and cellulitis, respectively [27]. On light microscopy, however, crystals appear as clumps of shiny nonbirefringent globules, and with alizarin red S stain, the clumps appear red-orange [28,29]. If hydroxyapatite is suspected, alizarin red S stain must be requested specifically from the laboratory as it is not a routine component of the crystal analysis. Calcium oxalate crystals can also induce an inflammatory arthritis. This is generally seen in patients on long-term hemodialysis [30,31], but may also be seen in young patients with primary oxalosis [27]. Synovial fluid typically reveals characteristic bipyramidal crystals as well as polymorphic forms [27].

It is important to note that even in the presence of crystals, infection must be considered because crystals can be seen concomitantly with a septic joint.

Other crystals include cryoimmunoglobulins in patients with multiple myeloma and essential cryoglobulinemia [32], and cholesterol crystals in patients with chronic inflammatory arthropathies, such as rheumatoid arthritis. Cholesterol crystals are a nonspecific finding and appear as platelike structures with a notched corner.
The Gram stain is performed as with other body fluids. It should be performed as soon as possible to screen for the presence of bacteria. It has been reported that the sensitivity of synovial fluid Gram stain in septic arthritis ranges between 50% and 75% for nongonococcal infection and less than 10% for gonococcal infection [26]. Specificity is much higher; this suggests that a positive Gram stain, despite a negative culture, should be considered evidence of infection. In fact, it is not uncommon for only the Gram stain to be positive in the setting of infection [26]. However, the absence of bacteria by the Gram stain does not rule out a septic process.

Synovial fluid in general should be cultured routinely for aerobic and anaerobic bacterial organisms. A positive culture confirms septic arthritis. In certain circumstances (e.g., in chronic monoarticular arthritis), fluid may be cultured for the presence of mycobacteria, fungus, and spirochetes. If disseminated gonorrhea is suspected, the laboratory must be notified because the fluid should be plated directly onto chocolate agar or Thayer–Martin medium. Just as Gram stain of synovial fluid in gonococcal infection is often negative, so too is synovial fluid culture. Synovial fluid culture is positive approximately 10% to 50% of the time, versus 75% to 95% of the time for nongonococcal infection [26]. However, cultures of genitourinary sites and mucosal sites in gonococcal infection are positive approximately 80% of the time [33]. Therefore, when suspicion of gonococcal arthritis is high (e.g., in a young, healthy, sexually active individual with a dermatitis-arthritis syndrome), the diagnosis must often be confirmed by a positive culture from the urethra, cervix, rectum, or pharynx.

In addition to documenting infection and identifying a specific organism, synovial fluid culture can be useful in determining antibiotic sensitivities and subsequent treatment. Furthermore, serial synovial fluid cultures can help in assessing response to therapy. For example, a negative follow-up culture associated with a decrease in synovial fluid polymorphonuclear cell count is highly suggestive of improvement.

Other studies on synovial fluid (e.g., glucose, protein, lactate dehydrogenase, complement, and immune complexes) are generally not helpful. Shmerling et al. [34] observed that synovial fluid glucose and protein were “highly inaccurate.” The synovial fluid glucose and protein misclassified effusions as inflammatory versus noninflammatory 50% of the time. In contrast, synovial fluid cell count and differential were found to be reliable and complementary; sensitivity and specificity of cell count was 84% for both and for the differential was 75% and 92%, respectively.
Of note, there are special stains for synovial fluid that can be helpful as the clinical picture warrants; these include Congo red staining for amyloid arthropathy. Amyloid deposits display an apple-green birefringence with polarized light \cite{35}. Prussian blue stain for iron deposition may reveal iron in synovial lining cells in hemochromatosis \cite{19}. However, neither of these studies should be considered a routine component of synovial fluid analysis.

Section 2

MINIMALLY INVASIVE MONITORING
TODD W. SARGE
A key difference between intensive care units (ICUs) and other hospital units is the level of detail with which patients are routinely monitored. This careful monitoring alerts the health care team to changes in the patient’s severity of illness—helping to both diagnose disease and assess prognosis. Careful monitoring also helps the health care team safely apply therapies such as volume resuscitation, vasoactive infusions, and mechanical ventilation.

This chapter deals with the routine, predominantly noninvasive monitoring that is often done for many patients in ICUs. It examines the indications for, the technology of, and problems encountered with the routine monitoring of temperature, blood pressure, electrocardiographic (ECG) rhythm, ST segments, respiratory rate, and oxygen and carbon dioxide levels. In addition, it reviews noninvasive monitoring of tissue perfusion, with particular attention to gastric tonometry, sublingual capnometry, and transcutaneous oxygen and carbon dioxide monitoring.

MONITORING SYSTEMS

When ICUs came into being in the late 1950s, nurses monitored patients’ vital signs manually or intermittently. Continuous measurement was either unavailable or necessitated invasive procedures. However, nearly all routine vital signs can now be monitored accurately, noninvasively, and continuously. As a result, patients now are monitored more intensively and continuously in the ICU than in any other part of the hospital, with the possible exception of the operating room.

Over the past decades, the trend for monitoring systems has been toward multipurpose systems that integrate monitoring of a variety of parameters. Multipurpose systems eliminate the need for multiple,
freestanding devices—reducing clutter and improving workflow ergonomics at the bedside. These systems also interface with critical care information systems to provide more efficient data management, quality improvement reporting, and in some cases prospective data-driven alerts.
TEMPERATURE MONITORING

Temperature abnormalities of the critically ill are associated with significant morbidity and mortality [1] (see Chapters 184 and 185)—making it clinically important to recognize an abnormal temperature. In one surgical ICU study, rectal temperatures on admission were normal in only 30% of patients, were above 37.6°C in 38%, and were below 36.8°C in 32% [2]. An abnormal temperature is frequently the earliest clinical sign of infection, inflammation, central nervous system dysfunction, or drug toxicity. Unfortunately, the type of thermometer and the site where the temperature is taken can affect the accuracy of this vital measurement. Clinicians should understand the impact of the thermometer type and the measurement site on how to interpret the patient’s reported temperature.

Indications for Temperature Monitoring

The Society of Critical Care Medicine’s Task Force on Guidelines’ recommendations for care in a critical care setting grades temperature monitoring as an essential service for all critical care units [3]. Critically ill patients are at high risk of temperature dysregulation because of debility, impaired control of temperature, use of sedative drugs, and a high frequency of infection. All critically ill patients should have core temperature measured at least intermittently. Patients with marked temperature abnormalities should be considered for continuous monitoring; patients undergoing active interventions to alter temperature, such as breathing heated air or using a cooling–warming blanket, should have continuous monitoring to prevent overtreatment or undertreatment of temperature abnormalities.

Measurement Sites

The goal of temperature measurements is generally to estimate core temperature—the deep body temperature that is carefully regulated by the hypothalamus so as to be independent of transient small changes in ambient temperature. Core temperature exists more as a physiologic concept than as the temperature with an anatomic location. An ideal measurement site would be protected from heat loss, painless, convenient to use, and would not interfere with the patient’s ability to move or communicate. No one location provides an accurate measurement of core temperature in all clinical circumstances.
Sublingual Temperature Measurements

Sublingual temperature measurements are convenient, but suffer numerous limitations. Although open-mouth versus closed-mouth breathing and use of nasogastric tubes do not alter temperature measurement [4], oral temperature is obviously altered if measured immediately after the patient has consumed hot or cold drinks. Falsely low oral temperatures may occur because of cooling from tachypnea. Sixty percent of sublingual temperatures are more than 1°F lower than simultaneously measured rectal temperatures; 53% differ by 1°F to 2°F, and 6% differ by more than 2°F. Continuous sublingual measurement is not generally practical. Sublingual measurement is best suited for intermittent monitoring when some inaccuracy can be tolerated.

Axillary Temperature Measurements

Axillary temperatures are commonly used as an index of core temperature. Although some studies indicate close approximation of the axillary site with pulmonary artery temperatures [5], temperatures average 1.5°C to 1.9°C lower than tympanic temperatures [6]. Positioning the sensor over the axillary artery may improve accuracy. The accuracy and precision of axillary temperature measurements are less than at other sites [6], perhaps due in part to the difficulty of maintaining a good probe position.

Rectal Temperature Measurements

Rectal temperature is the most widely accepted method for measuring core temperature in clinical use. Before a rectal thermometer is inserted, a digital rectal examination should be performed because feces can blunt temperature measurement. Readings are more accurate when the sensor is passed more than 10 cm (4 inches) into the rectum. Rectal temperature correlates well in most patients with distal esophageal, bladder, and tympanic temperatures [7]. Rectal temperatures typically respond to induced changes in temperature more slowly than other central measurement sites [8]. Many practitioners recommend against rectal manipulation in patients with neutropenia. Additionally, reusable, electronic, sheath-covered rectal thermometers have been associated with the transmission of *Clostridium difficile* and vancomycin-resistant *Enterococcus*, so disposable probes are generally preferred.
Esophageal Temperature Measurements

Esophageal temperature is usually measured with an electric, flexible temperature sensor. On average, esophageal temperatures are 0.6°C lower than rectal temperatures \[9\]. However, the measured temperature can vary greatly depending on the position of the sensor in the esophagus. In the proximal esophagus, temperature is influenced by ambient air \[10\]. During hypothermia, temperatures in different portions of the esophagus may differ by up to 6°C \[10\]. Because of the proximity of the distal esophagus to the great vessels and heart, the distal esophageal temperature responds rapidly to changes in core temperature \[11\]. Changes in esophageal temperature may inaccurately reflect changes in core temperature when induced temperature change occurs because of the inspiration of heated air, gastric lavage, or cardiac bypass or assist \[11\].

Tympanic Temperature Measurements

Health care providers can measure tympanic temperature with specifically designed thermometers that are commonly used in the ICU. However, several studies have demonstrated poor correlation with ICU patients’ core temperatures \[12,13\]. Accuracy depends in part on operator experience—but even when trained, experienced ICU nurses use tympanic thermometers, the variability in repeated measurements was more than 0.5°F in 20% of patients \[14\]. Unlike temporal artery measurements, which are not known to have complications, tympanic temperature measurements come with some risk. Perforation of the tympanic membrane and bleeding from the external canal due to trauma from the probe have been reported.

Temporal Artery Measurements

Temporal artery measurements are not known to have complications. Their accuracy is reviewed later in this chapter.

Urinary Bladder Temperature Measurements

Providers can easily measure the urinary bladder temperature with a specially designed temperature probe embedded in a Foley catheter \[6–8\]. In patients undergoing induced hypothermia and rewarming, bladder temperatures correlate well with great vessel and rectal temperatures \[7,8\]. Bladder temperature under steady-state conditions is more reproducible than those taken at most other sites \[7\].
Central Circulation Temperature Measurements

ICU practitioners can measure the temperature of blood in the pulmonary artery using a thermistor-equipped pulmonary artery catheter. The temperature sensor is located at the distal tip and can record accurate great vessel temperatures once the catheter is in place in the pulmonary artery. Pulmonary artery temperatures have generally been accepted as the gold standard for accurate measures of core temperature, although readings might be expected to differ from core temperature when heated air was breathed or warm or cold intravenous fluids were infused. However, this understanding may not be true for neurosurgical patients. A study of patients undergoing neurosurgical procedures with induced hypothermic circulatory arrest found that pulmonary arterial temperature measurement was not effective in assessing core brain temperature with a correlation coefficient of 0.63. A greater degree of correlation was found in bladder temperature [15]. Inserting a central venous thermistor specifically to monitor temperature is probably warranted only when other sites are felt to be unreliable and accurate, and rapid continuous temperature measurements are critical to the patient’s management.

Types of Thermometers

Mercury Thermometers

Although mercury thermometers were historically the most common type in clinical use, environmental and health concerns related to mercury have resulted in several state and local legislative efforts to phase out this type of thermometer. Mercury and other liquid–expansion-based thermometers can give a falsely low measurement when the thermometer is left in place for too short a period; falsely high temperatures result from failure to shake the mercury down.

Liquid Crystal Display Thermometers

Liquid crystal display (LCD) thermometers contain liquid crystals embedded in thin adhesive strips that are directly attached to the patient’s skin. LCD thermometers are most commonly applied to the forehead for ease of use and steady perfusion, but can be applied to any area of the skin. Like all skin temperature measurements, they may poorly reflect core temperature when the skin is hypoperfused or for patients with vasomotor instability. Forehead skin temperature is typically lower than core temperatures by 2.2°C [16], and changes in LCD
forehead temperature lag behind changes in core temperature by more than 12 minutes [17]. LCD skin thermometry is probably best used for patients with stable, normal hemodynamics who are not expected to experience major temperature shifts and in whom the trend of temperature change is more important than the accuracy of an individual measurement.

**Standard Digital Thermometers: Thermocouples and Thermistors**

Electric thermometers convert an electrical temperature signal into digital displays, frequently by use of thermocouples and thermistors as probes. Thermocouples and thermistors can be fashioned into thin wires and embedded in flexible probes that are suitable for placing in body cavities to measure deep temperature.

Thermocouples consist of a junction of two dissimilar metals. The voltage change across the junction can be precisely related to temperature. The measuring thermocouple must be calibrated against a second constant-temperature junction for absolute temperature measurements. In the range of 20°C to 50°C, thermocouples may have a linearity error of less than 0.1 [18].

Thermistors consist of semiconductor metal oxides in which the electrical resistance changes inversely with temperature. A linearity error of up to 4°C may occur over the temperature range of 20°C to 50°C, but this can be substantially reduced by mathematical adjustments and electrical engineering techniques [18]. Semiconductors measure temperature by taking advantage of the fact that the base-to-emitter voltage change is temperature dependent, whereas the collector current of the silicon resistor is constant. Thermistors are more sensitive, faster responding, and less linear than thermocouples or semiconductors [18].

---

**Infrared Emission Detection Thermometers**

**Tympanic Thermometers.** Commonly used in a hospital setting, infrared emission detection tympanic thermometers use a sensor that detects infrared energy emitted by the core temperature tissues behind the tympanic membrane. Infrared emissions through the tympanic membrane vary linearly with temperature. Operator technique is important: errors due to improper calibration, setup, or poor probe positioning can significantly alter temperatures [19]. Measurements are
most accurate when the measuring probe blocks the entrance of ambient air into the ear canal and when the midposterior external ear is tugged posterosuperiorly so as to direct the probe to the anterior, inferior third of the tympanic membrane. Studies are mixed on whether tympanic thermometers provide accurate core temperature measurements, ranging from a 4% clinically meaningful error rate [14] to a finding that 21% of tympanic readings might result in delays in therapy for or evaluation of fever [20].

**Temporal Artery Thermometers.** Infrared technology can also measure temperature over the temporal artery. A probe is passed over the forehead and searches for the highest temperature; some systems also scan the area behind the ear. An algorithm estimates ambient heat loss and blood cooling to calculate core temperature. The device is convenient, painless, and provides a rapid reading. Although one small study of normothermic patients found good correlation with pulmonary artery temperatures [5], another study in patients with a broader temperature range found that 89% of measurements differed from pulmonary artery temperatures by more than 0.5°C, the amount the authors had specified a priori as clinically significant [21].

**Selecting the Measurement Site**

The site used to monitor temperature must be an individualized choice, but certain generalizations can be made. When intermittent temperature measurement is all that is clinically needed (e.g., in routine monitoring), or the consequences of inaccurate measurement are low, rectal or sublingual measurement may be preferred. If less accuracy is required, tympanic, temporal, or axillary sites may be chosen. When more accurate measurement is needed, bladder, esophageal, and rectal temperatures in general appear to be most accurate and reproducible—although rectal temperatures may lag behind other temperatures when the patient’s status is changing quickly [7,13]. However, routine measurement of esophageal temperatures would necessitate inserting an esophageal probe in all patients. In addition, small changes in probe position can affect the accuracy of esophageal measurements, so this mode is probably best used in patients undergoing active, aggressive temperature management in centers with substantial experience with the modality. Meanwhile, rectal probes may be extruded or may be refused by patients. The third option, bladder temperature monitoring, is simplified by the fact that many critically ill patients have an indwelling Foley catheter. Monitoring the bladder temperature for these patients requires only a thermistor-equipped catheter. Patients with a thermistor-tipped pulmonary artery catheter already in place require no additional temperature monitoring.
Patient Safety and Temperature Monitoring

Therapeutic hypothermia is increasingly prevalent in ICU settings (Chapter 184). Some devices used to induce hypothermia are closed-looped systems. Since core temperature probes can fail (e.g., dislodgement of a rectal probe to a position outside the patient), practitioners should consider monitoring core temperature from two sites when temperature is being actively manipulated.
ARTERIAL BLOOD PRESSURE MONITORING

The first recorded blood pressure measurement occurred in 1733 and—somewhat surprisingly—was intraarterial pressure monitoring. The Reverend Stephen Hales placed a 9-foot brass tube in a horse’s crural artery and found a blood pressure of about 8 feet 3 inches. This was obviously not clinically applicable. In the mid-1800s, Carl Ludwig recorded the first arterial pressure waveforms, but it was not until 1881 that the first noninvasive blood pressure recordings were made. In 1896, Riva-Rocci developed and popularized the mercury sphygmomanometer, which was then adopted and disseminated at least in part by Harvey Cushing. In 1905, Korotkoff developed techniques for detecting diastolic pressure by listening for what are now called Korotkoff sounds. More clinical techniques for direct blood pressure measurement by intraarterial cannula were developed in the 1930s and popularized in the 1950s [22]. These measurements were soon accepted as representing true systolic and diastolic pressures.

Since that time, a variety of invasive and alternative indirect methods have been developed that equal and even surpass auscultation in reproducibility and ease of measurement. This section examines the advantages and disadvantages of various methods of arterial pressure monitoring and provides recommendations for their use in the ICU.

Noninvasive (Indirect) Blood Pressure Measurement

Providers can indirectly monitor blood pressure using a number of techniques, most of which describe the external pressure applied to block blood flow to an artery distal to the occlusion. These methods therefore actually detect blood flow, not intraarterial pressure, although one method describes the pressure required to maintain a distal artery with a transmural pressure gradient of zero. These differences in what is actually measured are the major points of discrepancy between direct and indirect measurements.

Indirectly measured pressures vary depending on the size of the cuff used. Cuffs of inadequate width and length can provide falsely elevated readings. Bladder width should equal 40% and bladder length at least 60% of the circumference of the extremity measured [23]. Anyone who makes indirect pressure measurements must be aware of these factors and carefully select the cuff to be used.
Manual Methods

Auscultatory (Riva-Rocci) Pressures

The traditional way to measure blood pressure involves inflating a sphygmomanometer cuff around an extremity and auscultating over an artery distal to the occlusion. Sounds from the vibrations of the artery under pressure (Korotkoff sounds) indicate systolic and diastolic pressures. The level at which the sound first becomes audible is taken as the systolic pressure. The point at which there is an abrupt diminution in or disappearance of sounds is used as diastolic pressure. This method, still commonly used in the ICU, yields an acceptable value in most situations. Its advantages include low cost, time-honored reliability, and simplicity. Disadvantages include operator variability, susceptibility to environmental noise, and the absence of Korotkoff sounds when pressures are very low. Auscultatory pressures also correlate poorly with directly measured pressures at the extremes of pressure [24].

Manual Oscillation Method

When a cuff is slowly deflated and blood first begins to flow through the occluded artery, the artery’s walls begin to vibrate. This vibration can be detected as an oscillation in pressure and has served as the basis for the development of several automated blood pressure monitoring devices. However, it also continues to be used in manual blood pressure measurement. The first discontinuity in the needle movement of an aneroid manometer indicates the presence of blood flow in the distal artery and is taken as systolic pressure [25]. The advantages of the oscillation method are its low cost and simplicity. The disadvantages include the inability to measure diastolic pressure, poor correlation with directly measured pressures [25], and lack of utility in situations in which Riva-Rocci measurements are also unobtainable. Aneroid manometers may also be inaccurate: in one study, 34% of all aneroid manometers in use in one large medical system gave inaccurate measurements, even when more lenient standards were used than those advocated by the National Bureau of Standards and the Association for the Advancement of Medical Instrumentation [26]. In the same survey, 36% of the devices were found to be mechanically defective—pointing out the need for regular maintenance. Although the manometers themselves can also be used for auscultatory measurements, oscillometric readings probably
provide no advantage over auscultation in the ICU.

**Palpation, Doppler, and Pulse Oximetric Methods**

Systolic pressures can be measured via any method that detects flow in a distal artery as the blood pressure cuff is slowly deflated. Palpation of the radial artery is the most commonly used technique; it is most useful in emergency situations in which Korotkoff sounds cannot be heard and an arterial line is not in place. The inability to measure diastolic pressure makes the palpation method less valuable for ongoing monitoring. In addition, palpation obtains no better correlation with direct measurements than the previously described techniques. In one study, variation from simultaneously obtained direct pressure measurements was as high as 60 mm Hg [24]. Like other indirect methods, palpation tends to underestimate actual values to greater degrees at higher levels of arterial pressure. Any method which detects blood flow distal to a sphygmomanometer cuff may be used in this fashion. Doppler machines are commonly used and may be particularly useful in situations where the pulse is not palpable or environmental noise precludes auscultation. Pulse oximeters have been similarly used and correlate well with other methods; the point at which a plethysmographic trace appears is taken as the systolic pressure [27].

**Automated Methods**

Automated indirect blood pressure devices operate on one of several principles: Doppler flow, infrasound, oscillometry, volume clamp, arterial tonometry, and pulse wave arrival time.

**Doppler Flow**

Systems that operate on the Doppler principle take advantage of the change in frequency of an echo signal when there is movement between two objects. Doppler devices emit brief pulses of sound at a high frequency that are reflected back to the transducer [28]. The compressed artery exhibits a large amount of wall motion when flow first appears in the vessel distal to the inflated cuff. This causes a change in frequency of the echo signal, known as a *Doppler shift*. The first appearance of flow in the distal artery represents systolic pressure. In an uncompressed artery, the small amount of motion does not cause a change in frequency of the reflected signal. Therefore, the disappearance of the Doppler shift in the echo signal represents diastolic pressure [29].

**Infrasound**
Infrasound devices use a microphone to detect low-frequency (20 to 30 Hz) sound waves associated with the oscillation of the arterial wall. These sounds are processed by a minicomputer, and the processed signals are usually displayed in digital form [30].

Oscillometry

Oscillometric devices operate on the same principle as manual oscillometric measurements. The cuff senses pressure fluctuations caused by vessel wall oscillations in the presence of pulsatile blood flow [31]. Maximum oscillation is seen at mean pressure, whereas wall movement greatly decreases below diastolic pressure [32]. As with the other automated methods described, the signals produced by the system are processed electronically and displayed in numeric form.

Volume Clamp Technique

The volume clamp method avoids the use of an arm cuff. A finger cuff is applied to the proximal or middle phalanx to keep the artery at a constant size [33]. The pressure in the cuff is changed as necessary by a servocontrol unit strapped to the wrist. The feedback in this system is provided by a photoplethysmograph that estimates arterial size. The pressure needed to keep the artery at its unloaded volume can be used to estimate the intraarterial pressure [34]. There have been a number of studies examining this method in the past decade, mostly in the anesthesia literature. This method has been shown to be reliable in patients at risk of hypotensive episodes, but has variable results in critically ill patients [35]. Limitations include a lag time of 7.5 to 10 seconds and inaccuracies associated with peripheral vasoconstriction from vasopressors, hypothermia, or collagen vascular disorders.

Arterial Tonometry

Arterial tonometry provides continuous noninvasive measurement of arterial pressure, including pressure waveforms. It slightly compresses the superficial wall of an artery (usually the radial). Pressure tracings obtained in this manner are similar to intraarterial tracings. A generalized transfer function can convert these tracings to an estimate of aortic pressure [36]. This method has not yet achieved widespread clinical use. One available system studied in ICU patients had approximately one-third of mean arterial pressure (MAP) readings which differed by ≥10 mm Hg compared with intraarterial pressure measurements and was associated with significant drift during the course of the study [37]. However, more studies of a different system reported
more accurate readings in patients undergoing anesthesia [38], including those with induced hypotension [39].

Utility of Noninvasive Blood Pressure Measurements

Only four of the methods described previously (infrasound, oscillometry, Doppler flow, volume clamp) are associated with significant clinical experience. Of these, methods that use infrasound technology correlate least well with direct measures of arterial blood pressure [31,40]. Therefore, infrasound is rarely used in systems designed for critical care.

Although they have not been consistently accurate, automated methods have the potential to yield pressures as accurate as values derived by auscultation. Commonly used oscillometric methods can correlate to within 1 mm Hg of the directly measured group average values [31] but may vary substantially from intraarterial pressures in individual subjects, particularly at the extremes of pressure. One study revealed as good a correlation with directly measured pressures as Riva-Rocci pressures have traditionally obtained [31]. Another study demonstrated that MAPs determined by auscultation were extremely close to those measured by automated devices [41].

When volume clamp methods using a finger cuff have been compared with standard methods [42,43], these devices have been found to respond rapidly to changes in blood pressure and give excellent correlation in group averages. In one study looking at a large number of measurements, 95% of all measurements using this method were within 10 mm Hg of the directly measured values [44]. Studies by Aitken et al. [43] and Hirschl et al. [42] demonstrated acceptable correlation of volume clamp technique with systolic pressures measured directly. However, other studies have shown clinically significant differences between the volume clamp technique and invasively measured pressures in patients undergoing anesthesia [45].

One of the proposed advantages of automated noninvasive monitoring is patient safety. Avoiding arterial lines eliminates the risk of vessel occlusion, hemorrhage, and infection. Automated methods, however, have complications of their own. Ulnar nerve palsies have been reported with frequent inflation and deflation of a cuff [46]. Decreased venous return from the limb and eventually reduced perfusion to that extremity can also be seen when the cuff is set to inflate and deflate every minute [46,47].

In summary, automated noninvasive blood pressure forms a major
component of modern critical care monitoring. Oscillometric and Doppler-based devices are adequate for frequent blood pressure checks in patients without hemodynamic instability, in patient transport situations in which arterial lines cannot be easily used, and in the severely burned patient, in whom direct arterial pressure measurement may lead to an unacceptably high risk of infection [48]. Automated noninvasive blood pressure monitors have a role for following trends of pressure change [49] and when group averages, not individual measurements, are most important. In general, they have significant limitations for patients with rapidly fluctuating blood pressures and may diverge substantially from directly measured intraarterial pressures. Given these limitations, critical care practitioners should be wary of relying solely on these measurements for patients with rapidly changing hemodynamics or in whom very exact measurements of blood pressure are important.

**Direct Invasive Blood Pressure Measurement**

Direct blood pressure measurement is performed with an intraarterial catheter. Chapter 7 reviews insertion and maintenance of arterial catheters. Here, we discuss the advantages and disadvantages of invasive monitoring compared with noninvasive methods.

Arterial catheters contain a fluid column that transmits the pressure back through the tubing to a transducer. A low-compliance diaphragm in the transducer creates a reproducible volume change in response to the applied pressure change. The volume change alters the resistance of a Wheatstone bridge and is thus converted into an electrical signal. Most systems display the pressure in both wave and numeric forms.

**Problems in Direct Pressure Monitoring**

**System-Related Problems.** Several technical problems can affect the measurement of arterial pressure with intraarterial catheters. Transducers must be calibrated to zero at the level of the heart. Improper zeroing can lead to erroneous interpretation. Thrombus formation at the catheter tip can occlude the catheter, making accurate measurement impossible. This problem can be largely eliminated by using a 20-gauge polyurethane catheter, rather than a smaller one, with a slow, continuous heparin flush [50], although this can be associated with heparin-induced thrombocytopenia [51]. Because movement may interrupt the column of fluid and prevent accurate measurement, the patient’s limb should be immobile during readings.

The frequency response of the transducer system is a phenomenon not only of transducer design but also of the tubing and the fluid in it. The length, width, and compliance of the tubing all affect the system’s
response to change. Small-bore catheters are preferable because they minimize the mass of fluid that can oscillate and amplify the pressure [52]. The compliance of the system (the change in volume of the tubing and the transducer for a given change in pressure) should be low [52]. In addition, bubbles in the tubing can affect measurements in two ways. Large amounts of air in the measurement system dampen the system response and cause the system to underestimate the pressure [53]. This is usually easily detectable. Small air bubbles cause an increase in the compliance of the system and can significantly amplify the reported pressure [52,53].

**Arterial Catheter Infections.** Recent data challenge the classical perception that arterial catheters are less likely to become infected [54] than central venous catheters. A prospective cohort study examined 321 arterial and 618 central venous catheters and found that arterial catheter colonization occurred with similar incidence to central venous catheter colonization [55]. Another recent study found similar results [56]. There is good evidence to support a link between the incidence of catheter colonization and catheter-related bloodstream infections [57]. Although one study suggested that full barrier precautions did not reduce the incidence of arterial line infection, interpretation of this trial is complex [58]. Taken together, the weight of evidence suggests that arterial catheters are an important potential source for infection of the critically ill patient and should be treated similar to central venous catheters in this setting. A recent study documented wide national variation in aseptic practices in arterial line insertion [59].

Finally, the location within the hospital where the procedure is performed is important as catheters placed in non-ICU locations may be associated with an increased risk of colonization versus those placed in the ICU [55].

**Site Selection.** The radial artery is the most common site of arterial cannulation for pressure measurement. This site is accessible and can be easily immobilized to protect both the catheter and the patient. The major alternative site is the femoral artery. Both sites are relatively safe for insertion [60,61]. The ulnar, brachial, dorsalis pedis, and axillary arteries are also used with some frequency [62]. Mechanical complications such as bleeding and nerve injury are discussed in Chapter 7. How should a provider choose a site? Although there are a number of theoretical considerations about comparing blood pressures from one site to another, there are little data from critically ill patients. A systematic review of 19,617 radial, 3,899 femoral, and 1,989 axillary cannulations found that serious complications occurred infrequently (<1% of cannulations) and were similar between all sites [62]. In 14 septic surgical patients on vasopressors, radial pressures were significantly lower than
femoral arterial pressures. In 11 of the 14 patients, vasopressor dose was reduced based on the femoral pressure without untoward consequences; after vasopressors were discontinued, radial and femoral pressures equalized. The authors concluded that clinical management based on radial artery pressures may lead to excessive vasopressor administration [63]. Similar significant differences in systolic pressures between the radial and femoral sites were found in the reperfusion phase of liver transplantation, although MAPs did not differ [64]. However, another somewhat larger observational study of critically ill patients [65] found no clinically meaningful differences in blood pressures between the sites. Although data are sparse, MAP readings between the radial and femoral sites are probably interchangeable in many or most patients. There may be a preference toward using femoral arterial pressure readings in patients with vasopressor resistant shock, but this decision should be balanced by the risks of the femoral approach.

Should the risk of infection drive site selection? The data are mixed. Earlier work suggested that there was no difference in infection rates between the femoral and radial sites [62]. More recently, a prospective observational study of 2,949 catheters in the ICU found that the incidence of catheter-related bloodstream infection was significantly higher for femoral access (1.92/1,000 catheter-days) than for radial access (0.25/1,000 catheter-days) (odds ratio, 1.9; \( p = 0.009 \)). Localized skin infections were also significantly increased in femoral versus radial arterial catheters. In addition, femoral arterial catheter bloodstream infections may have an increased association with gram-negative bacteria when compared to the radial site, similar to previous data from central venous catheters [66].

Advantages

Despite technical problems, direct arterial pressure measurement offers several advantages. Arterial lines actually measure the end-on pressure propagated by the arterial pulse. In contrast, indirect methods report the external pressure necessary to obstruct flow or to maintain a constant transmural vessel pressure. Arterial lines can also detect pressures at which Korotkoff sounds are either absent or inaccurate. Arterial lines provide a continuous measurement, with heartbeat-to-heartbeat blood pressures. In situations in which frequent blood drawing is necessary, indwelling arterial lines eliminate the need for multiple percutaneous punctures. Finally, analysis of the respiratory change in systolic or pulse
pressure may provide important information on cardiac preload and fluid responsiveness.

Conclusions

Indirect methods of measuring the blood pressure estimate the arterial pressure by reporting the external pressure necessary to either obstruct flow or maintain a constant transmural vessel size. Arterial lines measure the end-on pressure propagated by the arterial pulse. Direct arterial pressure measurement offers several advantages for many, but not all, patients. Although an invasive line is required, the reported risk of complications is low [62]. Arterial lines provide heartbeat-to-heartbeat measurements, can detect pressures at which Korotkoff sounds are either absent or inaccurate, and do not require repeated inflation and deflation of a cuff. In addition, they provide easy access for phlebotomy and blood gas sampling, and they may provide additional information about cardiac status. However, particular care should be taken with aseptic insertion technique and line site maintenance, since the reported incidence of arterial line infection approaches that of central venous catheterization. Regardless of the method used, the MAP should generally be the value used for decision-making for most critically ill patients.
ELECTROCARDIOGRAPHIC MONITORING

Almost all ICUs in the United States routinely perform continuous ECG monitoring. Continuous ECG monitoring combines the principles of ECG, which have been known since 1903, with the principles of biotelemetry, which were first put into practical application in 1921 [67]. Here we review the principles of arrhythmia monitoring, automated arrhythmia detection, and the role of automated ST segment analysis.

ECG monitoring in most ICUs is done over hard-wired apparatus. Skin electrodes detect cardiac impulses and transform them into an electrical signal, which is transmitted over wires directly to the signal converter and display unit. This removes the problems of interference and frequency restrictions that can be seen with telemetry systems.

Arrhythmia Monitoring in the ICU

Continuous ECG is generally considered the standard of care for all critically ill patients in intensive care, regardless of whether the patient’s primary admitting diagnosis is related to a cardiac problem [68]. Approximately 20% of patients in a general ICU have significant arrhythmias, mostly atrial fibrillation or ventricular tachycardia [69]. There is also a substantial incidence of arrhythmia following major surgery [70]. Although no studies address whether monitoring for arrhythmias in a general ICU population alters outcomes, this monitoring is generally accepted and considered standard care [68]. In postmyocardial infarction patients, on the other hand, the data are compelling. Arrhythmia monitoring was shown to improve the prognosis of patients admitted to the ICU for acute myocardial infarction (AMI) many years ago [71]. It has been a standard of care in the United States since that time. Although ventricular tachycardia and fibrillation after myocardial infarction have declined in frequency over the years, they still occur in about 7.5% of patients [72]. Monitoring enables the rapid detection of these potentially lethal rhythms.

Evolution of Arrhythmia Monitoring Systems for Clinical Use

After ICUs implemented continuous ECG monitoring, practitioners recognized some deficiencies with the systems. Initially, the responsibility for arrhythmia detection was assigned to specially trained coronary care nurses. Despite this, several studies documented that manual methods failed to identify arrhythmias, including salvos of VT, in
This failure was probably due to an inadequate number of staff nurses to watch the monitors, inadequate staff education, and faulty monitors [74]. Subsequently, monitors equipped with built-in rate alarms that sounded when a preset maximum or minimum rate was detected proved inadequate because some runs of VT are too brief to exceed the rate limit for a given time interval [73,75]. Ultimately, computerized arrhythmia detection systems were incorporated into the monitors. The software in these systems is capable of diagnosing arrhythmias based on recognition of heart rate, variability, rhythm, intervals, segment lengths, complex width, and morphology [76]. These systems have been validated in coronary care and general medical ICUs [73,77]. Computerized arrhythmia detection systems are well accepted by nursing personnel, who must work most closely with them [78].

**Ischemia Monitoring**

Just as simple monitoring systems can miss episodes of VT and ventricular fibrillation, they can fail to detect significant episodes of myocardial ischemia. This is either because the episode is asymptomatic or because the patient’s ability to communicate is impaired by intubation or altered mental status. ECG monitoring systems with automated ST segment analysis have been devised to attempt to deal with this problem.

In most ST segment monitoring systems, the computer initially creates a template of the patient’s normal QRS complexes. It then recognizes the QRS complexes and the J points of subsequent beats and compares an isoelectric point just before the QRS with a portion of the ST segment 60 to 80 milliseconds after the J point [79]. It compares this relationship to that of the same points in the QRS complex template. The system must decide whether the QRS complex in question was generated and conducted in standard fashion or whether the beats are aberrant, which negates the validity of comparison. Therefore, an arrhythmia detection system must be included in all ischemia monitoring systems. Standard systems can monitor three leads simultaneously. These leads are usually chosen to represent the three major axes (anteroposterior, left-right, and craniocaudal). The machine can either display these axes individually or sum up the ST segment deviations and display them in a graph over time [79].

Automated ST segment analysis has gained widespread popularity among cardiologists. Since 1989, the American Heart Association has recommended that ischemia monitoring be included in new monitoring
systems developed for use in the coronary care unit [80]. In patients admitted for suspected acute coronary syndromes, ischemia is both frequently silent and strongly associated with adverse events after discharge [68]. Although noting that no randomized clinical trials document improved patient outcomes when automated ST segment monitoring is used to detect ischemia, the American Heart Association recommends ST segment monitoring for patients with a number of primary cardiac issues (e.g., acute coronary syndromes), based on expert opinion. The guidelines make no statement regarding ST segment monitoring for ICU patients [68].

Newer Techniques

Because conventional three-lead monitoring detects only about one-third of transient ischemic events in patients with unstable coronary syndromes [81], some authors have advocated the use of continuous 12-lead ECG systems in the care of acute coronary syndromes. However, continuous 12-lead ECG monitoring can be impractical given the large number of leads required, patient discomfort, interference with medical procedures, and susceptibility to motion artifact. Some systems based on the dipole hypothesis of vectorcardiography allow the derivation of a 12-lead ECG from four recording electrodes and a reference electrode. Good correlation has been demonstrated between the EASI system and traditional 12-lead ECG in detection of ST segment deviation in acute myocardial ischemia and also in analyzing cardiac rhythm [82]. Other proposed enhancements to continuous ECG monitoring include signal-averaged ECG, QT dispersion, QT interval beat-to-beat variability, and heart rate variability [83]. Although associated with subsequent arrhythmic events, these have not yet reached common clinical use.

Technical Considerations

As with any other biomedical measurement, technical problems can arise when monitoring cardiac rhythms. Standards have been devised to guide manufacturers and purchasers of ECG monitoring systems [84].

The possibility of electrical shock exists whenever a patient is directly connected to an electrically operated piece of equipment by a low-resistance path. Electrical shocks would most commonly occur with improper grounding of equipment when a device such as a pacemaker is in place. Necessary precautions to avoid this potential catastrophe include (a) periodic checks to ensure that all equipment in contact with the patient is at the same ground potential as the power ground line; (b) insulating exposed lead connections; and (c) using appropriately grounded electrical outlets [85]. Each hospital’s biomedical engineering department should have a documented preventive maintenance plan for
all equipment in the unit.

The size of the ECG signal is important for accurate recognition of cardiac rate and rhythm. Several factors may affect signal size. The amplitude can be affected by a mismatch between the skin-electrode and preamplifier impedance. The combination of high skin-electrode impedance, usually the result of poor contact between the skin and electrode, with low-input impedance of the preamplifier can decrease the size of the ECG signal. Good skin preparation, site selection, and conducting gels can promote low skin-electrode impedance. A high preamplifier input impedance or the use of buffer amplifiers can also improve impedance matching and thereby improve the signal obtained. Another factor that affects complex size is critical damping, the system’s ability to respond to changes in the input signal. An underdamped system responds to changes in input with displays that exaggerate the signal, called overshoot. An overdamped system responds slowly to a given change and may underestimate actual amplitude. The ECG signal can also be affected by the presence of inherent, unwanted voltages at the point of input. These include the common mode signal, a response to surrounding electromagnetic forces; the direct current skin potential produced by contact between the skin and the electrode; and a potential caused by internal body resistance. Finally, the ECG system must have a frequency response that is accurate for the signals being monitored. Modern, commercially available systems have incorporated features to deal with each of these problems.

Personnel

The staff’s ability to interpret the information received is crucial to effective ECG monitoring [80]. Primary interpretation may be by nurses or technicians under the supervision of a physician. All personnel responsible for interpreting ECG monitoring should have formal training developed cooperatively by the hospital’s medical and nursing staffs. At a minimum, this training should include basic skills for proper lead placement, ECG interpretation, and arrhythmia recognition. Hospitals should also establish and adhere to formal protocols for responding to and verifying alarms. Finally, a physician should be available in the hospital to assist with interpretation and make decisions regarding therapy.

Principles of Telemetry

Intensive care patients frequently continue to require ECG monitoring after they are released from the ICU, and many postoperative critical care patients begin mobilization while in the ICU. At this point, increased mobility is important to allow physical and occupational therapy as well
as other rehabilitation services. Telemetry systems can facilitate this.

*Telemetry* means measurement at a distance and biomedical telemetry consists of measuring various vital signs, including heart rhythm, and transmitting them to a distant terminal [86]. Telemetry systems in the hospital consist of four major components [86]: (a) A signal transducer detects heart activity through skin electrodes and converts it into electrical signals; (b) a radio transmitter broadcasts the electrical signal; (c) a radio receiver detects the transmission and converts it back into an electrical signal; and (d) the signal converter and display unit present the signal in its most familiar format. Continuous telemetry requires an exclusive frequency so the signal can be transmitted without interruption from other signals, which means the hospital system must have multiple frequencies available to allow simultaneous monitoring of several patients. The telemetry signal may be received in one location or simultaneously in multiple locations, depending on staffing practices. The signal transducer and display unit should also be equipped with an automatic arrhythmia detection and alarm system to allow rapid detection and treatment of arrhythmias. Notably, telemetry systems may be subject to interference by cellular phones [87] or other radio equipment. Telemetry systems may also transmit over existing 802.11-type wireless networks.

---

**Summary**

Continuous ECG monitoring is usually considered the standard of care for all critically ill ICU patients [68]. Because ICU staff can miss a large percentage of arrhythmias when they use monitors without computerized arrhythmia detection systems, these computerized systems should be standard equipment for ICUs, especially those which care for patients with AMI. It appears that computerized monitoring devices can also detect a significant number of arrhythmias not detected manually in noncardiac patients and a concerning percentage of these lead to an alteration in patient care. Automated ST segment analysis facilitates the early detection of ischemic episodes. Telemetry provides close monitoring of recuperating patients while allowing them increased mobility.
RESPIRATORY MONITORING

Critical care personnel should monitor several primary respiratory parameters, including respiratory rate, tidal volume or minute ventilation, and oxygenation for critically ill patients. Routine monitoring of arterial carbon dioxide levels would be desirable, but the technology for monitoring these parameters is not yet developed enough to consider mandatory continuous monitoring. Among mechanically ventilated patients, many physiologic functions can be monitored routinely and continuously by the ventilator. This section does not discuss monitoring by the mechanical ventilator (see Chapter 30) but examines devices that might be routinely used to monitor the aforementioned parameters continuously and noninvasively.

Respiratory Rate, Tidal Volume, and Minute Ventilation

Clinical examination of the patient often fails to detect clinically important changes in respiratory rate and tidal volume [88]. Physicians, nurses, and hospital staff frequently report inaccurate respiratory rates, possibly because they underestimate the measurement’s importance [89]. In another study, ICU staff had a greater than 20% error more than one-third of the time when the recorded respiratory rate was compared with objective tracings [90]. This is particularly surprising since the respiratory rate is an especially important predictor of outcomes for many severity of illness scores such as the APACHE prediction system [91]. In fact, respiratory rate has been called “the neglected vital sign” [92]. Providers’ clinical assessment of tidal volume and minute ventilation is similarly inaccurate [93]. Therefore, objective monitoring must be used because clinical evaluation is inaccurate.

Impedance Monitors

ICUs commonly use impedance monitors to measure respiratory rates and approximate tidal volume. These devices typically use ECG leads and measure changes in impedance generated by the change in distance between leads as a result of the thoracoabdominal motions of breathing. Obtaining a quality signal requires placing the leads at points of maximal change in thoracoabdominal contour or using sophisticated computerized algorithms. Alarms can then be set for high and low rates or for a percentage drop in the signal that is thought to correlate with a decrease in tidal volume.

In clinical use, impedance monitors can suffer confounding problems.
They have failed to detect obstructive apnea when it has occurred and falsely detected apnea when it has not [94,95]. About one-third of all apnea alarms from this technology are false-positives [96]. In situations with moving patients, they are even less accurate for the quantification of respiratory rate [97]. Impedance monitors alone are poor detectors of obstructive apnea because they may count persistent chest wall motion as breaths when the apneic patient struggles to overcome airway obstruction [94,95]. In general, respiratory rate monitoring in the ICU results in a very high fraction of clinically irrelevant alarms: in one study, only 4% of respiratory alarms were deemed clinically relevant [98]. Although impedance monitors offer the advantage of being very inexpensive when ECG monitoring is already in use, they lack accuracy when precise measurements of apnea, respiratory rate, airflow, or tidal volume are required.

Respiratory Inductive Plethysmography

Respiratory inductive plethysmography (RIP) measures changes in the cross-sectional area of the chest and abdomen that occur with respiration and processes these signals into respiratory rate and tidal volume. This technology may be familiar to providers and patients because it is often used in polysomnograms. Typically, two elastic bands with embedded wires are placed above the xiphoid and around the abdomen. As the cross-sectional area of the bands changes with respiration, the self-inductance of the coils changes the frequency of attached oscillators. These signals are generally calibrated to a known gas volume, or may be internally calibrated so that further measurements reflect a percentage change from baseline rather than an absolute volume. RIP can accurately measure respiratory rate and the percentage change in tidal volume, as well as detect obstructive apneas [99–101]. RIP has been used to follow lung volumes in patients undergoing high-frequency oscillatory ventilation [102]. These measurements are often more accurate than impedance measurements [95]. However, some studies have found problems with RIP’s estimation of lung volumes. Notably, RIP must be calibrated against a known gas volume in order to provide tidal volume estimates. This calibration is not always accurate and may result in errors of >10% for 5% to 10% of patients even in highly controlled circumstances [99,103]. In mechanically ventilated patients, RIP had significant measurement drift (25 cm³ per minute) and imprecise volume estimates. Only about two-thirds of tidal volume estimates were accurate to within 10% of the reference value [104].

In addition to displaying respiratory rate and percentage change in tidal volume, RIP can provide asynchronous and paradoxical breathing measurements and alarms, which are common during early weaning and
may be helpful for predicting respiratory failure [105]. The noninvasive nature of the tidal volume measurement may be helpful for patients in whom technical problems or leaks make it difficult to directly measure expired volume (e.g., patients with bronchopleural fistulas). In addition, RIP can display changes in functional residual capacity, which permits health care providers to assess the effects of changing positive end-expiratory pressure (PEEP) or response to bronchodilator therapy. Providers can determine the presence and estimation of the amount of auto (intrinsic) PEEP by observing the effect of applied (extrinsic) PEEP on functional residual capacity [106], with the caveats noted earlier regarding possible inaccuracy of volume measurements.

RIP systems are available with central monitoring station configurations, which have been used in noninvasively monitored respiratory care units; these units have allowed ICU-level patients to be safely moved to a less labor-intensive level of care [107]. Compared with impedance methods, RIP is more accurate and offers a variety of other useful measurements but is less convenient and more expensive.

Other Methods

Although health care providers can also use pneumotachometers, capnographs, and electromyography to accurately measure respiratory rate, these methods are not commonly used in the ICU. A pneumotachometer requires complete collection of exhaled gas and, therefore, either intubation or use of a tight-fitting face mask is not practical simply for monitoring. A second alternative, capnography, works exceedingly well as a respiratory rate monitor. Because it does not require intubation or a face mask, it can be a useful tool in many circumstances. Capnography is discussed in more detail later in this chapter. A third option, surface electromyography of respiratory muscles, can be used to calculate respiratory rate accurately [108] but cannot detect obstructive apnea or provide a measure of tidal volume. Electromyography works well for infants but presents difficulties in adults, especially in obese adults and those with edema.

Recently, substantial research has focused on better ways to noninvasively monitor respiratory rate. All of these need clinical validation in a critical care setting, but examples of potentially emerging technologies include mechanical contact sensors placed in patient beds or pillows, acoustical respiratory monitoring, photoplethysmography, and monitoring based on the humidity of exhaled gas.
Measurements of Gas Exchange

Pulse Oximetry

Clinical estimation of hypoxemia is exceptionally unreliable [109,110]. Pulse oximeters measure the saturation of hemoglobin in the tissue during the arterial and venous phases of pulsation and mathematically derive arterial saturation. A meta-analysis of 74 oximeter studies suggests that these estimates are usually accurate within 5% of simultaneous gold standard measurements [111]. However, up to 97% of physicians and nurses who use pulse oximeters do not understand their underlying fundamental principles [112]. This section reviews the essential technology involved in pulse oximetry and practical problems that limit its use.

Theory. Oximeters distinguish between oxyhemoglobin and reduced hemoglobin on the basis of their differential absorption of light. Oxyhemoglobin absorbs much less red (±660 nm) and slightly more infrared (±910 to 940 nm) light than nonoxygenated hemoglobin. Oxygen saturation thereby determines the ratio of red to infrared absorption. When red and infrared light are directed from light-emitting diodes (LEDs) to a photodetector across a pulsatile tissue bed, the absorption of each wavelength by the tissue bed varies cyclically with pulse. During diastole, absorption is due to the nonvascular tissue components (e.g., bone, muscle, and interstitium) and venous blood. During systole, absorption is determined by all of these components and arterialized blood. The pulse amplitude accounts for only 1% to 5% of the total signal [113]. Thus, the difference between absorption in systole and diastole is in theory due to the presence of arterialized blood. The change in the ratio of absorption between systole and diastole can then be used to calculate an estimate of arterial oxygen saturation. Absorption is typically measured hundreds of times per second. Signals usually are averaged over several seconds and then displayed numerically. The algorithm used for each oximeter is determined by calibrations from human volunteers. Most oximeters under ideal circumstances measure the saturation indicated by the pulse oximeter (SpO₂) to within 2% of arterial oxygen saturation [114].

Cooximeters perform measurements on whole blood obtained from an artery or a vein. They frequently measure absorbance at multiple wavelengths and compute the percentage of oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin (COHb) in total hemoglobin based on different absorption spectra. They are mostly free of the artifacts that limit the accuracy of tissue oximeters and are regarded as a gold standard by which other methods of assessing
saturation can be measured.

**Technology.** Many manufacturers market pulse oximeters. Because of the variety of manufacturers, the numerous algorithms used, and the diverse patient populations studied, it is difficult to generalize from studies performed with one particular instrument, with its specific version of software, in one defined group of patients, to critically ill patients in general. The reader should always check with an oximeter’s manufacturer before generalizing the following discussion to his or her oximeter and patient population.

**Problems Encountered in Use.** Because pulse oximeters are ubiquitous, all ICU providers must understand their limitations. A meta-analysis of problems encountered in pulse oximetry trials identified severe hypoxemia, dyshemoglobinemia, low perfusion states, skin pigmentation, and hyperbilirubinemia as having the potential to affect the accuracy of pulse oximeter readings [111]. Any process that affects or interferes with the absorption of light between the LEDs and photodetector alters the quality of pulsatile flow, or changes the hemoglobin that may distort the oximeter’s calculations. Pulse oximeters should be able to obtain valid readings in 98% of patients in an operating room or postanesthesia care unit [115]. Table 27.1 lists the problems that must be considered in clinical use.

**Calibration.** Manufacturers use normal volunteers to derive pulse oximeter calibration algorithms. This creates three problems. First, manufacturers use different calibration algorithms, which results in a difference in SpO<sub>2</sub> of up to 2.7% between different manufacturers’ oximeters used to measure the same patient [116]. Second, the alternative manufacturers have defined SpO<sub>2</sub> differently for calibration purposes. Calibration may or may not account for the interference of small amounts of dyshemoglobinemia (e.g., methemoglobin or COHb). For example, if an oximeter is calibrated on the basis of a study of nonsmokers with a 2% COHb level, the measured SpO<sub>2</sub> percentage would differ depending on whether the value used to calibrate SpO<sub>2</sub> included or excluded the 2% COHb [116]. Third, it is difficult, for ethical reasons, for manufacturers to obtain an adequate number of validated readings in people with an SpO<sub>2</sub> of less than 70% to develop accurate calibration algorithms in this saturation range. Most oximeters give less precise readings in this saturation range [117]. Unless better calibration algorithms become available, oximeters should be considered unreliable when SpO<sub>2</sub> is less than 70%, although this may have little clinical impact since emergent intervention is usually required for all SpO<sub>2</sub> readings <70%.

**Measurement sites.** Careful sensor positioning is crucial for obtaining accurate results from a pulse oximeter [118]. Practitioners can obtain accurate measurements from fingers, forehead, and earlobes. The response time from a change in the partial pressure of arterial oxygen (PaO<sub>2</sub>) to a change in displayed SpO<sub>2</sub> is delayed for finger and toe probes compared to ear, cheek, or glossal probes [119,120]. Forehead edema, wetness, and head motion may result in inaccurate forehead SpO<sub>2</sub> values [121]. Motion and perfusion artifacts are the greatest problems with finger or toe measurements. The earlobe is believed to be the site least affected by vasoconstriction artifact [122], but paradoxically the finger may give a better signal at times of hypoperfusion [111].

**Fingernails.** Long fingernails may prevent correct positioning of the finger pulp over the LEDs used in inflexible probes and therefore produce inaccurate SpO<sub>2</sub> readings without affecting the pulse rate [123]. Synthetic nails have also produced erroneous results [114]. Adhesive tape, even when placed over both sides of a finger, did not affect measured SpO<sub>2</sub> [124]. Since pulse oximetry depends fundamentally on color, nail polish may falsely lower SpO<sub>2</sub>. In a 1988 study, blue, green, and black polish showed greater decreases than red or purple [125]. However, a 2002
study with a newer generation oximeter did not find this effect [126]. In addition, placing the probe sideways across the fingernail bed appeared to ameliorate any effect of fingernail polish in one study [127].

**Skin color.** The effect of skin color on SpO2 was assessed in a study of 655 patients [128]. Although patients with the darkest skin had significantly less accurate SpO2 readings, the mean inaccuracy in SpO2 (compared with cooximetry) between subjects with light skin and those with the darkest skin was only 0.5%, a clinically insignificant difference. Pulse oximeters, however, encountered difficulties in obtaining readings in darker skinned patients; 18% of patients with darker skin triggered warning lights or messages versus 1% of lighter skinned patients. A study of 284 patients with a newer generation oximeter also found that skin color did not affect measurement accuracy. Poor-quality readings were found more often in darker skinned patients, although this was a rare event (<1% of all patients) [129]. Thus, dark skin may prevent a measurement from being obtained, but when the oximeter reports an error-free value, the value is generally accurate enough for clinical use [130].

**Ambient light.** Ambient light that affects absorption in the 660- or 910-nm wavelengths, or both, may affect calculations of saturation and pulse. Xenon arc surgical lights [131], fluorescent lights [132], and fiberoptic light sources [133] have caused falsely elevated saturation but typically are accompanied by obvious dramatic elevations in reported pulse. An infrared heating lamp [134] has produced falsely low saturations and a falsely low pulse, and a standard 15-W fluorescent bulb resulted in falsely low saturation without a change in heart rate [135]. Interference from surrounding lights should be suspected by the presence of pulse values discordant from the palpable pulse or ECG, or changes in the pulse-saturation display when the probe is transiently shielded from ambient light with an opaque object. Most manufacturers have now modified their probes to minimize this problem. Studies report that ambient lighting has little or no effect on newer generation oximeters [136], although this varies among manufacturers [137].

**Hyperbilirubinemia.** Bilirubin’s absorbance peak is maximal in the 450-nm range but has tails extending in either direction [138]. Bilirubin, therefore, does not typically affect pulse oximeters that use the standard two-diode system [138,139]. However, it may greatly interfere with the measurement of saturation by cooximeters. Cooximeters typically use four to six wavelengths of light and measure absolute absorbance to quantify the percentage of all major hemoglobin variants. Serum bilirubin values as high as 44 mg per dL had no effect on the accuracy of pulse oximeters but led to falsely low levels of oxyhemoglobin measured by cooximetry [138].
**Dyshemoglobinemias.** Conventional (two-diode) pulse oximeters cannot detect the presence of methemoglobin, COHb, or fetal hemoglobin. Fetal hemoglobin may confound readings in neonates but is rarely a problem in adults. On the other hand, acquired methemoglobinemia—although uncommon—is seen in routine practice, largely due to the use of methemoglobinemia-inducing drugs such as topical anesthetics [140]. Because methemoglobin absorbs more light at 660 nm than at 990 nm, it affects pulse oximetry readings [141]. Moreover, higher levels of methemoglobin tend to bias the reading toward 85% to 90% [142]. COHb is typically read by a two-diode oximeter as 90% oxyhemoglobin and 10% reduced hemoglobin [143], resulting in false elevations of SpO₂. A gap between pulse oximetry and PO₂ or cooximetrically measured oxygen saturation may suggest elevated COHb levels, particularly in patients with smoke inhalation or potential carbon monoxide poisoning [144]. Because COHb may routinely be 10% among smokers, pulse oximetry may fail to detect significant desaturation in this group of patients. Oxygen saturation in smokers, when measured by cooximetry, was on average 5% lower than pulse oximetric values [145]. Hemolytic anemia may also elevate COHb up to 2.6% [146]. Because other etiologies of COHb are rare in the hospital and the half-life of COHb is short, this problem is unusual in the critical care setting except in newly admitted patients, patients with active hemolysis, or those on COHb-inducing drugs such as sodium nitroprusside [147]. More recently, some pulse oximeters that use multiwavelength technology have been able to successfully report methemoglobin and COHb levels [148].

**Anemia.** Few clear data are available on the effect of anemia on pulse oximetry. In dogs, there was no significant degradation in accuracy until the hematocrit was less than 10% [149]. In one study of humans who had hemorrhagic anemia, there appeared to be little effect on pulse oximetry accuracy [150].

**Lipids.** Patients with elevated chylomicrons and those receiving lipid infusions may have falsely low SpO₂ because of interference in absorption by the lipid [151]. This also affects cooximetry and may lead to spurious methemoglobin readings [152].

**Glycohemoglobin A₁C.** A study of 261 patients with type 2 diabetes mellitus showed that a HbA₁c greater than 7% leads to an overestimation of SpO₂ by an average of 2.3% when compared to those with a HbA₁c less than 7% [153].

**Hypothermia.** Good-quality signals may be unobtainable in 10% of hypothermic patients [154]. The decrease in signal quality probably results from hypothermia-induced vasoconstriction. When good-quality
signals could be obtained, SpO₂ differed from cooximetry-measured saturation by only 0.6% [154] in one series.

**Intravascular dyes.** Methylene blue, used to treat methemoglobinemia, has a maximal absorption at 670 nm and therefore falsely lowers measured SpO₂ [155]. Indocyanine green and indigo carmine also lower SpO₂, but the changes are minor and brief [156]. Fluorescein has no effect on SpO₂ [156]. Because of the rapid vascular redistribution of injected dyes, the effect on oximetry readings typically lasts only 5 to 10 minutes [157]. Patent V dye, which is used to visualize lymphatics in sentinel node mapping, confounds pulse oximetry, an effect which may persist for more than 90 minutes [158].

**Motion artifact.** Shivering and other motions that change the distance from diode to receiver may result in artifact. Oximeters account for motion by different algorithms. Some oximeters display a warning sign, others stop reporting data, and others display erroneous values. The display of a plethysmographic waveform rather than a signal strength bar helps to indicate to providers that artifact has distorted the pulse signal and lowered the quality of the SpO₂ reading. Newer generation oximeters appear to have significantly less susceptibility to motion artifact than earlier models [159].

**Hypoperfusion.** During a blood pressure cuff inflation model of hypoperfusion, most oximeters remained within 2% of control readings [160]. Increasing systemic vascular resistance and decreasing cardiac output can also make it harder to obtain a good-quality signal. In one series, the lowest cardiac index and highest systemic vascular resistance at which a signal could be detected were 2.4 L/min/m² and 2,930 dynes second/cm⁵/m², respectively [161]. Warming the finger [162] or applying a vasodilating cream [161] tended to extend the range of signal detection in individual patients. The oximeter’s ability to display a waveform and detect perfusion degradation of the signal was crucial for determining when the readings obtained were valid [160].

**Pulsatile venous flow.** In physiologic states in which venous and capillary flows become pulsatile, the systolic pulse detected by the oximeter may no longer reflect the presence of just arterial blood. In patients with severe tricuspid regurgitation, the measured saturation may be falsely low, especially with ear probes [163].
**Indications.** The Society of Critical Care Medicine considers pulse oximetry (or transcutaneous oxygen measurement) essential monitoring for all ICU patients receiving supplemental oxygen [164]. Unsuspected hypoxemia is common among critically ill patients. Sixteen percent of patients not receiving supplemental oxygen in the recovery room following general anesthesia have saturations of less than 90% [165]. In 35% of patients, saturations of less than 90% develop during transfer out of the operating room [166]. Because of the high frequency of hypoxemia among critically ill patients, the frequent need to adjust oxygen flow, and the unreliability of visual inspection to detect mild desaturation, oximeters should be used for most critically ill patients for routine, continuous monitoring. In one study that randomized more than 20,000 operative and perioperative patients to continuous or no oximetric monitoring, the authors concluded that oximetry permitted detection of more hypoxemic events, prompted increases in the fraction of oxygen in inspired gas, and significantly decreased the incidence of myocardial ischemia but did not significantly decrease mortality or complication rates [167].

Oximeters have been used in the ICU for reasons other than continuous monitoring. For example, oximeters may be helpful during difficult intubations. Once desaturation occurs, attempts to intubate should be postponed until manual ventilation restores saturation. Note, however, that oximetry is not helpful for promptly detecting inadvertent esophageal intubation because desaturation may lag significantly behind apnea in preoxygenated patients [168]. Oximeters can be useful for detecting systolic blood pressure (see arterial pressure monitoring earlier), and have been used in other clinical applications with varying degrees of success. Notably, a normal SpO2 reading should not be used to exclude pulmonary embolism [169].

**Capnography**

Capnography involves the measurement and display of expired PCO2 concentrations. This section reviews the technology, the sources of differences between end-tidal PCO2 (EtCO2) and PaCO2, and the indications for capnography in the ICU.

**Technology.** The partial pressure of expired CO2 is usually determined by infrared absorbance or mass spectrometry. The infrared technique relies on the fact that carbon dioxide has a characteristic absorbance of infrared light, with maximal absorbance near a wavelength of 4.28 mm. A heated wire with optical filters is used to generate an infrared light of appropriate wavelength. When carbon dioxide passes between a focused beam of light and a semiconductor photodetector, an electronic signal
can be generated that, when calibrated, accurately reflects the partial pressure of the tested gas.

A mass spectrometer bombards gas with an electron stream. The ion fragments that are generated can be deflected by a magnetic field to detector plates located in precise positions to detect ions that are characteristic of the molecule being evaluated. The current generated at the detector can be calibrated to be proportional to the partial pressure of the molecule being evaluated.

The two techniques have different strengths. Mass spectrometers can detect the partial pressures of several gases simultaneously and can monitor several patients at once. Infrared techniques measure only PCO$_2$ and are usually used on only one patient at a time. The calibration and analysis time required for mass spectrometry is significantly longer than with infrared techniques. Infrared systems respond to changes in approximately 100 milliseconds, whereas mass spectrometers take 45 seconds to 5 minutes to respond [170]. Although costs vary widely, mass spectrometers are in general far more expensive and are most frequently purchased to be the central component of a carbon dioxide monitoring system. In the operating room, mass spectrometry has the advantage of being able to measure the partial pressure of anesthetic gases, and the need for a technical specialist to oversee its operation can be more easily justified. For these reasons, mass spectrometry has achieved much more popularity in the operating room than in the ICU.

Gases can be sampled by mainstream or sidestream techniques. Mainstream sampling involves placing the capnometer directly in line in the patient’s respiratory circuit. All air leaving the patient passes through the capnometer. The sidestream sampling techniques pump 100 to 300 mL expired gas per minute through thin tubing to an adjacent analyzing chamber.

The mainstream method can be used only for patients who are intubated or wearing a tight-fitting laryngeal, face, or nose mask. Mainstream sampling offers the advantage of almost instantaneous analysis of sampled air, but it increases the patient’s dead space and adds weight to the endotracheal tube. Sidestream sampling removes air from the expiratory circuit, altering measurement of tidal volume. Slower aspirating flow rates and longer tubing lengths significantly worsen the ability to detect a rapid rise in carbon dioxide and cause delay between physiologic changes in the patient and the display of changes on the monitor [171]. When the delay exceeds the respiratory cycle time, the generated data are inaccurate [171]. Located near the mouth or nose, sidestream sampling lines are also prone to clogging with secretions, saliva, or water condensation. Sidestream sampling can be used in nonintubated patients to detect cyclic changes in carbon dioxide concentrations. Because of these issues, accurate sidestream sampling
requires short sampling tubes and attention to the possibility of clogged sample lines.

Differences Between End-Tidal and Arterial Carbon Dioxide. The PCO$_2$ of exhaled air measured at the mouth changes in a characteristic pattern for normal people that reflects the underlying physiologic changes in gas exchange (Fig. 27.1). During inspiration, the PCO$_2$ is negligible, but it rises abruptly with expiration. The rapid rise reflects mixing and the washout of dead space air with air from perfused alveoli, which contain higher levels of CO$_2$. A plateau concentration is reached after dead space air has been exhaled. The plateau level is determined by the mean alveolar PCO$_2$, which is in equilibration with pulmonary capillary PCO$_2$. The end-alveolar plateau level of PCO$_2$ measured during the last 20% of exhalation is the EtCO$_2$. In normal people at rest, the difference between EtCO$_2$ and PaCO$_2$ is ±1.5 mm Hg. A difference exists because of the presence of dead space and normal physiologic shunting. Changes in dead space or pulmonary perfusion alter ventilation–perfusion ratios and change the relationship between end-tidal and arterial PCO$_2$ values. As dead space increases, the EtCO$_2$ represents more the (lower) PCO$_2$ of nonperfused alveoli, thereby diverging from the PaCO$_2$ value. As perfusion decreases, fewer alveoli are perfused, creating a similar effect.
FIGURE 27.1 Normal and abnormal capnograms.
In the normal capnogram (A), on the right of the trace, the paper speed has been increased. The EF segment is inspiration. The FG segment reflects the start of expiration with exhalation of dead space gas. The GH segment is the alveolar plateau. End-tidal values are taken at point H. HI is the beginning of inspiration. In the abnormal capnograms, the alveolar plateau is distorted and the end-tidal point cannot be clearly determined because of cardiac oscillations (B), erratic breathing (C), and obstructive airway disease (D). ECG, electrocardiogram.

For most equipment, the EtCO₂ level is determined by a computerized algorithm. Because algorithms are imperfect, a waveform display is considered essential for accurate interpretation of derived values [171]. For slowly breathing patients, cardiac pulsations may cause the
intermittent exhalation of small amounts of air at the end of the lungs’ expiratory effort. This results in oscillations that may obscure the plateau phase. An irregular respiratory pattern or large increases in dead space can also cause distortion of the plateau phase. Visual inspection of traces can detect situations in which algorithms are prone to produce errors [170].

**Indications.** In the ICU, capnography is most useful for (1) detection of extubation, (2) determining the presence or absence of respiration, and (3) detecting return of spontaneous circulation after cardiac arrest. Such determinations do not require that EtCO₂ be measured accurately, only that changes be detected reliably. Alarms for apnea and tachypnea can be set and relied on, although capnography cannot discriminate between obstructive and central apnea. Capnography is a useful adjunct for detecting unintentional extubation, malposition of the endotracheal tube, or absence of perfusion. Cyclic variation of EtCO₂ is absent in esophageal intubation or disconnection from the ventilator [172], although pharyngeal intubation with adequate ventilation may produce a normal capnogram.

Capnography can demonstrate the return of circulation after cardiopulmonary arrest or bypass and is a useful indicator of endotracheal tube placement. In full cardiac arrest, EtCO₂ is low because of lack of perfusion; a rapid rise in EtCO₂ indicates return of circulation and successful delivery of CO₂ to the alveoli [173]. Capnography also detects esophageal intubation [174]. The American Heart Association 2015 Emergency Cardiovascular Care Guidelines include a Class I recommendation for using quantitative waveform capnography for verifying endotracheal tube placement after intubation for cardiac arrest. They also suggest consideration of using capnography to monitor CPR quality in real-time, titrate vasopressor therapy, and detect return of spontaneous circulation as a IIb recommendation. Finally, because EtCO₂ reflects cardiac output, the guidelines note that “failure to achieve an EtCO₂ of greater than 10 mm Hg by waveform capnography after 20 minutes of CPR may be considered as one component of a multimodal approach to decide when to end resuscitative efforts but should not be used in isolation” [175].

Can capnography be used as an approximation of arterial PaCO₂ for most critically ill patients? The answer is no. EtCO₂ measurements are unreliable indicators of PaCO₂ among critically ill patients. Since these patients undergo rapid changes in dead space fraction and pulmonary perfusion, the relationship of EtCO₂ to arterial PaCO₂ may change rapidly and unpredictably. In one study of anesthetized, stable, generally healthy
adults, PaCO\textsubscript{2} could not be reliably determined from end-tidal values [176]. In patients undergoing weaning from mechanical ventilation, EtCO\textsubscript{2} was also shown to have no predictable relationship to PaCO\textsubscript{2} [177]. Although end-tidal and arterial values correlated well ($r = 0.78$) and rarely differed by more than 4 mm Hg, changes in EtCO\textsubscript{2} correlated poorly with changes in arterial PCO\textsubscript{2} ($r^2 = 0.58$). Because of changes in dead space and perfusion, arterial and end-tidal measurements at times moved unpredictably in opposite directions. EtCO\textsubscript{2} values can also be altered depending on the site of sampling as shown in a study comparing sidestream versus mainstream sampling among critically ill patients. In that study, EtCO\textsubscript{2} differed from PaCO\textsubscript{2} by 13 mm Hg on average for mainstream sampling and 9.7 mm Hg for sidestream sampling [178]. Although theoretically attractive, the use of end-tidal carbon dioxide measurements to evaluate changes in ventilation–perfusion mismatch in response to ventilator changes has failed to yield consistent clinical benefits [179].

Capnography has been helpful in the operating room for detecting air and pulmonary embolism as well as malignant hyperthermia [170]. In these situations, the capnograph does not provide a diagnosis; it records a change that, if limits are exceeded, signals an alarm. The responsibility for accurately interpreting the subtleties of changes of the capnogram remains the task of an experienced physician.

**Conclusions.** Capnography should be used after cardiac arrest to confirm endotracheal tube placement, and should be considered for monitoring the quality of CPR during an arrest. It is also an accurate monitor of respiratory rate (unlike many other technologies). In general, it should not be used as a substitute for PaCO\textsubscript{2} monitoring because the relationship of PaCO\textsubscript{2} and EtCO\textsubscript{2} varies for patients with changing cardiac output, fluctuating respiratory function, or chronic lung disease. This is important between patients, but also within the same patient over time. Capnography has an accepted role in the operating room, where its value is increased because of its ability to help detect endotracheal tube malposition, air embolism, pulmonary embolism, and malignant hyperthermia, and where there is a highly skilled anesthesiologist immediately available to interpret subtle changes in the capnogram.
NONINVASIVE TISSUE PERFUSION MONITORING

Bedside providers usually monitor tissue perfusion based on clinical signs such as skin temperature and capillary refill time. However, several noninvasive technologies provide quantitative data about overall or regional tissue perfusion. Unlike most of the other monitoring technologies described in this chapter, clinical adoption of these techniques has been relatively limited and heterogeneous [180]. This section reviews three such technologies that measure local PCO$_2$ or PO$_2$: gastric tonometry, sublingual capnometry, and transcutaneous oxygen and carbon dioxide monitoring. Measurements from each of these techniques correlate with meaningful clinical outcomes such as patient survival.

Physiology: Why Regional PO$_2$ and PCO$_2$ Reflect Tissue Perfusion and not just Global Gas Exchange

At first glance, it would appear that measurement of regional PO$_2$ or PCO$_2$ in the skin, stomach, or tongue would reflect global gas exchange and might be used for noninvasive blood gas estimation. In some cases, this is true. In healthy adults, for example, transcutaneously measured PO$_2$ and PCO$_2$ (PtcO$_2$ and PtcCO$_2$) accurately reflect PaO$_2$ and PaCO$_2$ [181]. The measured transcutaneous values of oxygen and carbon dioxide are typically 10 mm Hg lower [182] and 5 to 23 mm Hg higher [183] than arterial values, respectively.

However, local PO$_2$ and PCO$_2$ therefore depend not only on global gas exchange, cardiac output, and oxygen content, but also on regional blood flow and oxygen delivery to the site of measurement. Under normal circumstances, oxygen delivery far exceeds consumption. In critical illness, however, regional hypoperfusion or inadequate regional delivery of oxygen may occur for any number of reasons: hypotension, regional vasoconstriction, low cardiac output states, anemia, vascular occlusion, etc. If there is no flow to the region, there can be no delivery of oxygen and no elimination of carbon dioxide by the vasculature—thus creating lower local PO$_2$ and higher local PCO$_2$ than in the arterial circulation.

When tissue is hypoperfused, local metabolism then further alters local PO$_2$ and PCO$_2$. As cellular processes use available oxygen for the
production of adenosine triphosphate (ATP), local $PO_2$ falls. When these cells use ATP faster than they replenish it, they liberate hydrogen ions ($H^+$) and reduce local pH. (Alternatively, cells may produce lactic acid through the anaerobic metabolic pathway.) These additional hydrogen ions are then buffered by tissue bicarbonate, generating $CO_2$ by the reaction:

$$H^+ + HCO_3^- \rightarrow H_2O_3 \rightarrow H_2O + CO_2.$$  

This increases the local $PCO_2$ above the corresponding global/arterial values [184]. For these reasons, local $PO_2$ and $PCO_2$ vary not only with global gas exchange, but also with local tissue perfusion and other factors.

**Gastric Tonometry**

Gastric tonometry, probably the most commonly used of the three perfusion monitoring techniques discussed in this section, assesses regional splanchic perfusion based on the stomach’s mucosal $PCO_2$. The splanchic circulation has several properties which make this region particularly useful to assess in critically ill patients. Early in the development of shock states, the splanchic circulation vasoconstricts, shunting cardiac output toward other core organs. Although this helps to prevent circulatory collapse, it may also result in intestinal mucosal ischemia—increasing the risk of gastric stress ulceration, mesenteric ischemia, and translocation of gut bacteria into the systemic circulation [185]. The gut is particularly sensitive to hypoperfusion and so may provide earlier warning of occult hypoperfusion than other vascular beds —leading some to liken it to a coal miner’s canary [186]. Gastric tonometry measures gastric luminal $PCO_2$ and estimates gastric intramucosal $PCO_2$ and pH (pHi).

**Technical Considerations**

**Development.** Early measurements of visceral mucosal pH required operative implantation of monitors and focused on the gallbladder, urinary bladder, and small bowel [187,188]. Development of silastic tubing [189]—which is exceptionally permeable to $O_2$ and $CO_2$—and confirmation that gases in tissue equilibrate rapidly with fluid in the lumen of a hollow viscus [190] allowed development of the modern gastrointestinal tonometer.

**Technique.** The upper gastrointestinal catheter is inserted with a standard technique for nasogastric tube placement, and placement is
confirmed radiographically. The stopcock is flushed with fluid to eliminate any trapped air, the balloon is filled to the manufacturer’s specifications with fluid, and the tonometer lumen is closed to the outside environment. The fluid is allowed to equilibrate with the fluid in the lumen of the organ being monitored, a process believed to require approximately 90 minutes, although formulas are available to correct the values obtained with 30 to 90 minutes of equilibration [191]. After adequate time for equilibration, the dead space (usually 1.0 mL) is aspirated and discarded, and the fluid in the balloon is completely aspirated under anaerobic conditions. An ABG sample is taken simultaneously, and both samples are sent for analysis. The PCO$_2$ of the tonometer sample is measured directly. Providers can then calculate an arterial/mucosal PCO$_2$ gap or, using the HCO$_3^-$ of arterial blood and the modified Henderson–Hasselbalch equation, pHi [192,193].

An air-based tonometer has also gained popularity. This device operates on the same principles as the saline-based tonometer, but automatically aspirates small amounts of air from a semipermeable balloon. This is substantially more convenient than the saline-based device, and allows semicontinuous measurement of gastric mucosal PCO$_2$. Results are generally similar to saline-based tonometry [194].

**Technical Limitations.** Several issues may confound the clinical use of gastric tonometry. Two of these apply only to saline-based tonometry. The fluid in the tonometer balloon requires 90 minutes for full equilibration with the fluid in the stomach. In a rapidly changing patient, this time window may not be appropriately timely. In addition, manufacturers calibrate blood gas analyzers to measure PCO$_2$ in blood, not saline. PCO$_2$ measurements in tonometer saline, therefore, may vary based on the blood gas analyzer used [195]. Other limitations apply to the general principle of measured gastric luminal PCO$_2$ to estimate mucosal perfusion. Tonometrically derived gastric pH$i$ can be affected by the acid-secretory status of the stomach. In one study, mean gastric pH$i$ was 7.30 in untreated normal volunteers but 7.39 in a similar group treated with ranitidine [196]. This was because the PCO$_2$ in the gastric fluid of the treated patients was 42 ± 4 mm Hg, compared with 52 ± 14 mm Hg in the untreated group. The difference in carbon dioxide content of the fluid is thought to be due to production of carbon dioxide by the conversion of secreted H$^+$ and HCO$_3^-$ into water and carbon dioxide. Enteral feeding
may also affect pH[i reading. Tube feedings may lead to increased production of carbon dioxide through the interaction of secreted hydrogen ions and HCO$_3^-$

Some suggest temporarily discontinuing tube feeds before doing pH[i measurements [197], although the PCO$_2$ effect appears to diminish after 24 hours of continuous feeding [198]. Finally, pH[i is a calculated variable which uses the systemic arterial bicarbonate value; this probably does not reflect regional perfusion [193]. The present consensus favors the use of arterial-gastric PCO$_2$ gap rather than pH[i [194,199].

**Clinical Usefulness and Limitations.** pH[i correlates well with a number of clinically important end points. Changes in pH[i during weaning from mechanical ventilation predict weaning failure [200]. Intraoperative and postoperative cardiac surgery patients have been particularly well studied, and in that group gastric pH[i appears to predict complications well [201,202]. Most importantly, pH[i predicts mortality of septic [203], acutely injured [204], and general ICU patients [205].

For a diagnostic tool to be *therapeutically* useful, however, we must be able to act on its results in a way that improves patient outcome [206]. Therapeutic protocols based on gastric tonometry have produced conflicting results. A randomized, controlled trial of 260 ICU patients, reported in 1992, found that gastric pH[i-based therapy had no effect on mortality of patients with a low admission pH[i but was associated with reduced mortality among patients with a normal admission pH[i [207]. However, the interpretation of this finding is severely limited because the authors did not analyze the results in an intention-to-treat fashion, thus abandoning many of the benefits of randomization [208], and 21 patients were withdrawn from the study due to protocol noncompliance by treating physicians. A subsequent randomized, controlled trial of 210 general ICU patients, reported in 2000, found no difference between intervention and control arms [209]. For patients with a normal initial pH[i, there was a nonsignificant trend toward increased 30-day mortality in the group treated based on pH[i. A 2005 study randomized 151 trauma patients to pH[i-driven therapy, splanchnic ischemia/reperfusion-based protocol, or usual care. The authors found no significant differences in mortality, organ dysfunction, ventilator days, or length of stay in an intention-to-treat analysis [210]. A recent meta-analysis of pH[i-driven therapy showed no reduction in-hospital or ICU mortality, length of stay, or days of intubation. It did however show a decrease in overall mortality in patients who presented with a normal pH[i [211].

**Alternative Regional PCO$_2$ Measurement: Sublingual Capnometry.** Sublingual capnometry operates on the same fundamental principles as gastric tonometry. A sensor is placed under the
tongue and CO₂ diffuses across a semipermeable membrane into a dye, which fluoresces differently based on CO₂ concentration. A fiberoptic cable transmits light of the appropriate wavelength and detects the resulting fluorescence, which is proportional to CO₂ concentration in the sensor [180]. Results from this technique correlate with gastric tonometry [212] and patient outcomes [213]. No randomized intervention trials based on sublingual capnometry have yet been published.

**Summary.** Although gastric tonometry predicts many important clinical outcomes, high-quality data do not support gastric tonometry–based resuscitation. At this time, it remains largely a research tool. Researchers are continuing to investigate the use of sublingual capnometry, a similar technology, as a potential resuscitation end point.

**Transcutaneous Oxygen and Carbon Dioxide Measurement in Adults**

Transcutaneous measurements of the partial pressures of oxygen (PtcO₂) and carbon dioxide (PtcCO₂) are frequently used for neonatal blood gas monitoring but have not gained widespread clinical acceptance in adult ICUs [180]. In adults, similar to gastric tonometry, PtcO₂ and PtcCO₂ reflect local tissue oxygen and carbon dioxide levels and therefore blur the boundary between assessment of global gas exchange and regional tissue perfusion monitoring. More recently, measurements of transcutaneous hemoglobin oxygen saturation (StO₂) have entered the research and clinical realms.

This section refers only to transcutaneous monitoring in adults.

**Technique**

Oxygen and carbon dioxide diffuse out of the capillaries, into the interstitium, and through the skin. The skin usually resists O₂ and CO₂ diffusion, but heating the skin promotes diffusion by changing the structure of the stratum corneum, shifting the oxygen dissociation curve, and promoting arterIALIZation of dermal capillaries [180]. Transcutaneous systems take advantage of these properties to measure partial pressures of oxygen (PtcO₂) and carbon dioxide (PtcCO₂). Typically, a unit less than 1 inch in diameter is attached with an airtight seal to the skin with an adhesive. An electrode heats the skin to improve gas exchange; a temperature sensor measures skin temperature at the skin surface and adjusts the heater to provide a constant temperature—typically about
44°C. Oxygen and carbon dioxide diffuse out of the capillaries into the interstitium and through the skin to measuring electrodes.

Technical Limitations

Because units use electrodes for partial pressure measurement, problems with calibration and electrode drift during prolonged monitoring can clearly alter measurements. Drift may alter readings by up to 12% over a 2-hour period [214]. Because of the heating requirement, probe sites must be changed at least every 4 hours to prevent burns [215]. Units must be recalibrated whenever the probe temperature is changed and every 4 to 6 hours to prevent artifact from electrode drift. Many units take 15 to 60 minutes to warm the skin and establish stable readings. Probes must be firmly attached to the skin, or leaks from the surrounding atmosphere lower PtcCO$_2$ and alter PtcO$_2$ values. Adhesion is a problem in diaphoretic patients.

Thick or edematous skin provides a diffusion barrier that amplifies differences between arterial and transcutaneous PO$_2$ and PCO$_2$. The longer the distance the gases must diffuse to be measured, the more important are the effects of temperature, perfusion, and local metabolism. This appears to be the fundamental reason why transcutaneous measurements are usually more closely related to arterial values in neonates than in adults. Edema, burns, abrasions, or scleroderma would all be expected to alter transcutaneous values.

Clinical Usefulness and Limitations

Because PtcO$_2$ and PtcCO$_2$ reflect local PO$_2$ and PCO$_2$, they change in response both to regional perfusion/oxygen delivery and to global derangements. In stable, healthy adults without hemodynamic or respiratory instability, PtcO$_2$ and PtcCO$_2$ accurately reflect PaO$_2$ and PaCO$_2$ [181,214]. The measured transcutaneous values of oxygen and carbon dioxide are typically 10 mm Hg lower [182] and 5 to 23 mm Hg higher [216] than arterial values, respectively. In stable patients, it may be reasonable to use transcutaneously measured values as surrogates for arterial PO$_2$ and PCO$_2$. However, systemic hypoperfusion due to low cardiac output, regional hypoperfusion due to sepsis or shock, and local hypoperfusion due to cutaneous vasoconstriction caused by medication or cold produces discrepancies. For these cases, transcutaneous
measurements cease to reflect arterial values and better track oxygen delivery and tissue metabolism [217]. For these reasons, many authors have argued against relying on PtcO₂ and PtcCO₂ to estimate arterial PO₂ and PCO₂ for critically ill adults [217,218].

Several studies have demonstrated the value of transcutaneous oxygen measurements as indices of perfusion or oxygen delivery. When PaO₂ remains constant, a decrease in PtcO₂ is probably due to changes in perfusion. Changes in local perfusion and metabolism may cause PtcO₂ values to fall to zero and PtcCO₂ values to climb to more than 30 mm Hg above arterial values [216]. During cardiac decompensation and arrest, PtcO₂ correlates best with cardiac output [219]. In hemorrhagic shock, the ratio of PtcO₂ to PaO₂ decreases, even though PaO₂ may remain normal [220]. Because the measurements are very sensitive to changes in flow, they can be useful in predicting or warning of imminent change before a blood pressure response is seen. In a small series of high-risk perioperative patients, declines in the PtcO₂/PaO₂ ratio predicted subsequent hemodynamic collapse [221]. Transcutaneous PtcO₂ also correlates with mortality. Among emergency department patients with severe sepsis or septic shock, PtcO₂ was lower in nonsurvivors than in survivors [222]. Among trauma patients, PtcO₂ values were significantly higher in survivors than in nonsurvivors (p < 0.001) with an area under the receiver operating characteristics curve of 0.74 for predicting in-hospital mortality [223].

Ongoing Development

More recent work has focused on the use of near-infrared spectroscopy to measure tissue hemoglobin oxygen saturation. This technique, rather than quantifying partial pressures of oxygen, instead measures the percent of microvascular hemoglobin saturated with oxygen. It has shown clinical correlations with invasive hemodynamic measures for those with sepsis [224] and severity of shock for trauma victims [225]. Further research is required to define the role of StO₂ as a potential resuscitation end point.

Summary

Transcutaneous monitors have little role in the ICU as simple tools to replace other means of measuring arterial gases. They predictably reflect arterial PO₂ and PCO₂ values only in hemodynamically stable patients,
who are least likely to demand intensive care or to benefit from ICU monitoring. As monitors of trends in PCO₂ and PO₂, they can be regarded as effective only in the sense that they typically do not produce false-negative alarms—that is, if the arterial values change, the transcutaneous values reflect the change. So many other factors, such as changes in tissue edema and perfusion, may result in alterations in transcutaneous trends that the supervising staff can initially determine only that something has changed. An accurate interpretation of the clinical event usually requires reassessment of either cardiac status or arterial gases.

Therefore, transcutaneous monitors are inadequate cardiac monitors and inadequate pulmonary monitors but are good cardiopulmonary monitors. When perfusion is stable, values reflect gas exchange. When gas exchange is stable, values reflect perfusion. When both are unstable, the results cannot be interpreted without additional information. The use of near-infrared spectroscopy to measure tissue hemoglobin oxygenation—StO₂—is a promising development, but one that requires further clinical study.

INTRODUCTION

The assessment and optimization of cardiac output (CO) has historically been considered important for the management of critically ill patients. The etiology of shock in a hypotensive patient may not be obvious clinically and is often multifactorial. In these circumstances, it is helpful to characterize what type of shock, i.e., distributive, cardiogenic, hypovolemic, is playing a role in a patient’s presentation as well as monitor their response to interventions, such as volume loading. Determination of CO is thought to be a critical component of this process and thus has long been a matter of interest to clinicians.

The physical examination can be unreliable for assessing hemodynamics of systolic heart failure [1] and for critically ill patients without recent myocardial infarction [2]. As such, more dependable measurements may be required to treat such patients optimally. Since its introduction [3], the flow-directed pulmonary artery catheter (PAC) has been useful for obtaining measurements of CO and has been used both diagnostically as well as to gauge response to treatment. Indeed, for many years, the PAC thermodilution technique was considered to be the “gold standard” of intensive care unit (ICU) hemodynamic measurement. However, this philosophy has been called into question over the last several decades in light of mounting evidence that clinicians may be using the PAC ineffectively [4] and that morbidity and mortality in a variety of clinical situations are not improved with its use [5–7], and in some cases may be worsened [8,9].

As the paradigm of hemodynamic monitoring for the critically ill has
steadily shifted away from PAC use, attention has turned to the study of alternative and less invasive methods of determining cardiac function. These methods can be divided into two broad categories: (1) direct measurement and optimization of CO and (2) indirect measurement of oxygen delivery and/or tissue perfusion as surrogates for CO. The goal of this research has been to develop feasible, minimally invasive techniques with accuracy for the ICU patient and in some cases, these studies have focused on adapting monitoring technology that is already routinely used in this patient population. In this chapter, we focus on several emerging technologies being used to determine CO and tissue perfusion in the ICU. We will conclude with a summary of practice recommendations and future directions.
CARDIAC OUTPUT

CO is the amount of blood flow through the cardiovascular system over a period of time. Conventionally, it is reported in liters per minute and can be normalized for a person’s body surface area to provide the cardiac index. In the normal patient, CO is directly related to that subject’s metabolic rate and oxygen consumption (VO₂). The fundamental principles of CO will be described in more detail elsewhere in this text. The therapies for a hypotensive patient with diminished CO (cardiogenic or obstructive shock) are fundamentally different from the therapies for a patient with diminished vascular tone (distributive shock). Therefore, accurate measurement of cardiac function can be a helpful guide for the effective treatment of hypotension.

Traditionally, a number of techniques have been used for the assessment of cardiac function. Jugular venous pulsations, S3 gallop, and skin temperature are physical examination findings that have all been used to estimate CO with mixed results [10–12]. Pulmonary artery occlusion pressure (PAOP) and central venous pressure (CVP) have also been used as surrogates for left and right ventricular end-diastolic volume, respectively. The PAOP is commonly used to establish the diagnosis of pulmonary venous hypertension or hypotension for the hypotensive patient and is often used to guide resuscitation, whereas Magder and colleagues [13,14] demonstrated that the CVP could provide useful information about the volume status of critically ill patients. Because the majority of the blood volume is in the systemic veins, and the right ventricle can be the major determinant of CO, some have argued that the CVP should receive more attention as the focus of hemodynamic resuscitation protocols [15]. Unfortunately, PAOP and CVP only represent the end-diastolic pressures of their respective chambers. These variables do not always reflect accurately end-diastolic volumes or equate with systolic function and CO. In addition, invasive assessment of PAOP [16,17] and clinical assessment of CVP [18] have been notoriously difficult to define accurately and reliably.

Over the last few decades, considerable research has been devoted to the accurate measurement of CO by minimally invasive means. At present, there exist several modalities, which are able to provide estimates of CO on a continuous or near-continuous basis. As described below, some have accumulated enough supporting data to warrant increasing use in clinical settings (esophageal Doppler [ED], pulse contour analysis [PCA], thoracic bioreactance) while the clinical usefulness of others is still unclear (partial carbon dioxide rebreathing) and will not be discussed further here.
Esophageal Doppler

Background

Ultrasound (US) creates images through the transmission of sound waves from a transducer and the subsequent measurement of sound waves which are reflected back. As the sound waves travel through the body, they are reflected back when they encounter adjacent structures or tissues which have different acoustic impedances. The degree of wave reflection is directly proportional to the magnitude of the difference in acoustic impedances between the adjacent structures such that interfaces between structures with highly different properties (i.e., blood and endocardium) will be reflected back to a greater degree. Image resolution and tissue penetration are dependent upon the frequency of the emitted sound wave such that higher frequency transducers provide superior image resolution at the expense of a reduced depth of penetration.

Motion-mode (M-mode), the most basic mode of US, represents the structures along the path of a single one-dimensional (1-D) vector. Sound waves reflected from this vector are displayed over time and its narrow scanning sector produces superior resolution for fast moving structures. Another clinically utilized mode of US is Doppler US that is used to calculate the velocity of a moving target, i.e., blood. This mode utilizes the Doppler shift principle, whereby a transmitted sound wave encountering a moving structure or fluid will reflect at a predictably different frequency based on the structure or fluid’s properties. For example, in a fluid-filled tube such as a blood vessel, the magnitude of Doppler shift will vary in direct proportion to the velocity of blood flow in the vessel. Thus, Doppler US can provide information on both the velocity and the direction of intravascular blood flow.

The most commonly used mode is two-dimensional (2-D). Real-time 2-D images are created when the US beam is continuously swept to and fro in an arc and multiple 1-D images are aligned. This allows movement of cardiac structures such as the myocardial walls to be observed. In a landmark study in 1974, Griffith and Henry [19] were able to visualize the heart’s structure and function in vivo using a handheld scanner that swept through a 30° arc at a speed of 30 cycles per second, along with real-time display and video recording. Although transthoracic echocardiography (TTE) was revolutionary in its ability to evaluate cardiac function noninvasively, it was often limited by body habitus and
an inability to visualize posterior cardiac structures. To overcome these limitations, Schluter and colleagues [20] were among the first to revolutionize the clinical use of transesophageal echocardiography (TEE) by attaching miniaturized transducers to a gastroscope, allowing structures not normally visualized on TTE to be clearly visible. Over time, as the value of cardiac US as a diagnostic tool became apparent, efforts have been made to improve its technical capabilities and clarity. This has led to the increasing use of both TTE and TEE in the ICU as minimally invasive monitoring modalities. As a separate chapter in this text focuses primarily on TTE, this chapter will cover ED and its uses in critically ill patients.

**Estimating Cardiac Output**

Transesophageal assessment of hemodynamics in critical care has evolved over time in parallel with advancements in technology. The initial esophageal probes possessed only Doppler functionality giving rise to the commonly used nomenclature esophageal Doppler. Later iterations successfully added M-mode capability such that both blood flow and aortic diameter could simultaneously be measured. The first use of ED in humans was described by Side and Gosling [21] in 1971 when they used a Doppler probe to measure CO by analyzing stroke volume (SV) in the descending aorta. The ED system estimates SV by modeling the aorta as a cylinder (Fig. 28.1A). Using this geometric model, the SV is calculated by multiplying the cross-sectional area (CSA) of the aorta by the stroke distance which is the length of the aorta that a given SV travels:

\[ SV = CSA \times \text{stroke distance} \]
FIGURE 28.1 Esophageal Doppler measures stroke volume (SV) in the descending aorta. A: The aorta can be modeled as a cylinder. SV can be estimated by multiplying the cross-sectional area of the cylinder by the stroke distance. B: The velocity time integral (VTI) estimates stroke distance. The VTI is quantified as the area under the waveform and represents the stroke distance. SV is then calculated: $SV = CSA \times \text{stroke distance}$.

As the aortic cross section closely approximates a circle, the CSA can be
calculated by measuring the diameter (D) of the aorta using M-mode or by estimating the diameter from nomograms in the absence of M-mode capability:

\[ CSA = \pi \left( \frac{D}{2} \right)^2 \]

The length that a SV travels is then estimated by measuring the velocity time integral (VTI) of the aortic jet by Doppler (Fig. 28.1B).

\[ \text{Stroke distance} = \text{VTI} \]

SV can then be estimated as follows:

\[ SV = \pi \left( \frac{D}{2} \right)^2 \times \text{VTI} \]

As this measurement of aortic blood flow does not account for the component of total SV that travels to the coronary, carotid, and subclavian arteries, a correction factor must finally be applied to estimate the total SV. When using ED, important inaccuracies can occur if the aortic diameter measurement has even a small error as this value is ultimately squared during the calculation of SV [22]. Therefore, some operators will estimate a surrogate of SV using the VTI measurement alone. Additionally, SV can be underestimated if the Doppler signal is measured from a plane that is not parallel to that of blood flow [23].

The majority of recent studies that have compared ED-derived CO to the “gold standard” of thermodilution have been performed in either intraoperative or postoperative settings and have revealed mixed results. One single-center study of 35 patients during off-pump coronary artery bypass graft surgery showed very poor correlation between the two techniques [24]. Other studies, including a meta-analysis of 11 trials, have shown that ED systems are better at following changes in CO in response to fluid challenges than they are at measuring the absolute CO [25–27]. As the ability to monitor the response to interventions is arguably as important as measuring actual CO, these data suggest that ED may be a useful tool in the perioperative setting. The authors of the meta-analysis also highlight that the poor reproducibility inherent in the thermodilution technique will likely affect the limits of agreement between ED systems and thermodilution even if ED systems were accurate [25]. This concept was described by Bland and Altman [28] and has important implications when comparing the accuracy of absolute CO measured by any system when compared to thermodilution.

Optimizing Cardiac Output using Esophageal Doppler
Beyond providing an estimate of CO, ED systems can provide information about the preload and the contractility of the heart. Singer et al. [29,30] analyzed the flow velocity waveform derived from an ED system and discovered that the corrected flow time (FTc) directly correlated with preload. Wallmeyer and colleagues [31] described a correlation between the peak velocity measured by Doppler and contractility measured by electromagnetic catheter measured flow. Singer et al. [32] further substantiated this finding by demonstrating that dobutamine infusions increased peak flow velocities measured by an ED system in a dose-dependent fashion. These observations suggest that an experienced operator may be able to extrapolate useful hemodynamic parameters, beyond the CO, through careful data synthesis. However, subsequent studies evaluating the utility of FTc have shown mixed results. In a medically critically ill patient population, a baseline FTc was poorly sensitive for discerning those who will be volume responsive and it significantly increased in some patients despite a lack of increase in CO [33,34].

Dynamic measurements of volume responsiveness have the best evidence supporting their utility for discriminating volume responsiveness. Monnet and colleagues [35] studied the utility of a passive leg raise (PLR) maneuver in a mechanically ventilated medically ill population and found that an increase in aortic blood flow ≥10% on ED could predict volume responsiveness with excellent accuracy. This study also showed that the change in aortic blood flow was a useful marker in those with arrhythmias and spontaneous ventilation, a population where other dynamic measurements of volume responsiveness have poor correlation [35–37].

**Clinical Utility of Esophageal Doppler**

The majority of studies which have examined the impact of ED on clinical outcomes focused on the perioperative setting. The transesophageal approach has distinct advantages over transthoracic in this setting including the ability to monitor continuously as well as to overcome limited access to the chest wall for TTE for most surgical patients. In 2006, a randomized double-blinded clinical trial of ED-guided intraoperative fluid resuscitation during colorectal surgery demonstrated that ED use was associated with earlier time to discharge, faster tolerance of a diet, and less need for inotropes [38]. Figus et al. [39] showed similar outcomes for patients undergoing reconstructive surgery and observed that although the total amount of fluid administered was not different between the two groups, the ED-guided group achieved a significantly lower net balance. Their findings were consistent with a recent meta-
analysis which suggested that a balanced fluid approach (net zero) for patients undergoing colorectal surgery resulted in less perioperative complications and shorter lengths of stay [40]. These data challenge the prevailing paradigm of perioperative care which has historically resulted in positive fluid balances. Accordingly, judicious fluid use and a closer scrutiny on fluid balance has become a cornerstone of the modern enhanced recovery after surgery (ERAS) programs [41–43]. As such, a minimally invasive method of estimating fluid responsiveness intraoperatively may be of considerable value during larger surgeries. Interestingly, however, when ED was examined in the context of an ERAS approach, its use did not confer clinical benefit despite better optimization of SV [44]. While far from conclusive, these data suggest that (1) as long as CO is adequate, further optimization may be unnecessary and/or (2) a net zero fluid balance can be achieved without any monitoring of CO in many surgical patients.

There are few studies which examine the clinical impact of ED use among critically ill patients outside of standard perioperative management. A small, single-center study of trauma patients with hemorrhagic shock demonstrated that ED-guided resuscitation decreased the incidence of occult shock and was associated with fewer infectious complications and significantly reduced hospital length of stay [45]. Although further studies are needed to confirm the clinical utility, it does suggest that ED can be a meaningful diagnostic tool in the ICU.

Advantages and Disadvantages of Esophageal Doppler

There are several potential advantages to using ED for hemodynamic monitoring in the critically ill (Table 28.1). First, as outlined above, ED systems provide continuous data, which allows for earlier recognition of hemodynamic deterioration or improvement in response to a therapeutic intervention. Additionally, an ED probe can be placed in minutes and has been associated with a low incidence of major iatrogenic complications [46–48]. Some data also suggest that once inserted, an esophageal probe can be left in situ safely for more than 2 weeks [49]. Finally, as the esophagus is a non-sterile environment, it is logical to assume that the infectious risk of an ED probe is minimal.

| TABLE 28.1 Advantages and Disadvantages of Esophageal Doppler for Cardiac Output Monitoring |
| Concept: Doppler probe measures stroke volume in the aorta |
Advantages
- Continuous monitoring
- Proximity to the aorta
- Quick placement
- Estimates CO and predicts volume responsiveness
- Low infection risk
- Can remain in place for 2 weeks

Disadvantages
- Unable to use on > 1 patient
- Requires intubation
- Need for repositioning

CO, cardiac output.

ED monitoring has a few potential disadvantages as well. Transesophageal monitoring cannot be used from patient to patient as readily as the transthoracic approach and, therefore, multiple devices would be required if more than one examination is needed at a given time and has cost implications. Also, ED can only be utilized in intubated patients and are contraindicated in patients with esophageal perforation or stricture. Finally, while ED probes can be left in for extended periods of time for continuous hemodynamic monitoring, they have been noted to be frequently dislodged despite best efforts to keep patients adequately sedated [45].

Future Research

While the use of critical care echocardiography is expanding, and existing literature has shown its use affects management, there are little data to suggest it alters outcomes. The current management paradigm for septic shock with acute respiratory distress syndrome (ARDS) involves early and aggressive volume resuscitation [50] coupled with avoidance of unnecessary fluid that may exacerbate lung injury and lengthen ventilation time [51]. ED assessment of fluid responsiveness may better achieve optimal fluid status than CVP and could lead to more refined resuscitation protocols that affect patient outcomes. Similarly, a greater focus on fluid balance for surgical patients as part of ERAS programs may involve more incorporation of this modality. As these programs evolve and disseminate, more robust analyses of their clinical impact will likely follow.

Ongoing advancements in echocardiography technology will also impact its role in the future of intensive care. A 5.5 mm disposable monoplane TEE device has recently been developed and preliminary studies show that it is easy to place, can be safely left in for up to 72
hours, and can have a significant impact on management of medical ICU patients [52]. This technology may lead to more widespread adoption of using continuous 2-D TEE in the future.

The optimal training method to establish competence in ED use also requires further investigation. While cardiology-based certifications have traditionally relied upon volume-based metrics to establish competency [53], the American College of Chest Physicians has recently developed a competency-based training course for critical care US [54]. This novel and pragmatic approach combines online material with sequential didactic seminars that progress from basic to more advanced material. Learners are then instructed to return to their practices and assemble a portfolio of images which can be remotely reviewed by expert ultrasonographers to ensure competence in image acquisition in a real-world environment. Once competence has been confirmed, learners are able to complete a final examination to obtain certification. Rigorous assessment of the success of this model may lead to more effective training methods for both fellows and practicing intensivists.

Pulse Contour Analysis

Background

PCA is another modality for measuring CO noninvasively that has been extensively studied. This method relies on the theory, first described by Frank in the early part of the 20th century, that SV and CO can be derived from the characteristics of an aortic pressure waveform [55]. Wesseling and colleagues [56] published in 1983 an algorithm to link mathematically SV and the pressure waveform. This original approach calculated SV continuously by dividing the area under the curve of the aortic pressure waveform by the aortic impedance. As aortic impedance varies among patients, it had to be measured using another modality, usually arterial thermodilution, to calibrate the PCA system prior to obtaining SV data. Aortic impedance, however, is not a static property. It is based upon the complex interaction of the resistive and compliant elements of each vascular bed, which are often dynamic, especially among hemodynamically unstable patients. Since the first PCA algorithm was introduced, several unique algorithms have been created to model accurately the properties of the human vascular system for use in PCA systems.
PCA involves the use of an arterial placed catheter with a pressure transducer, which can measure pressure tracings on a beat-to-beat basis. Such catheters are now routinely used in operating rooms and ICUs as they provide a continuous measurement of blood pressure that is superior to intermittent noninvasive measurements in hemodynamically unstable patients. These catheters are interfaced with a PCA system, which uses its unique algorithm to provide a continuously displayed measurement of CO. Thus, the reliability of a PCA system depends upon the accuracy of the algorithm that it employs. Because each algorithm is unique in the weight that it ascribes to each element of vascular conductivity, it has been impossible to ensure that a system will be able to reproduce the results of another system under similar conditions [57]. Keeping this in mind, one cannot conclude that all systems are equally reliable.

PiCCO (Pulsion SG, Munich, Germany) is a PCA system that has received considerable attention in the literature. Numerous studies have demonstrated a strong correlation between this system and pulmonary thermodilution for both critically ill and surgical patients [58–62]. Notably, this system did not require recalibration during these study periods, which were performed under static ventricular loading conditions. The system involves the placement of a central arterial catheter equipped with a pressure transducer and a thermistor for arterial thermodilution. The system is calibrated by injecting cold saline via a central venous catheter at the right atrium in a manner similar to pulmonary arterial thermodilution. Instead of using a thermistor in the pulmonary artery, however, the thermistor on the central arterial catheter allows for a transpulmonary thermodilution and calculation of CO. This initial value of CO is then used to calibrate the PCA system that is coupled to the arterial catheter. When compared to pulmonary artery thermodilution, the transpulmonary thermodilution method was found to be accurate, implying that it is an acceptable method for calibration of a PCA system [58–60].

A competitor PCA system known as the Flotrac (Edwards Lifesciences, LLC, Irvine, CA) has also been widely used in the intensive care setting. It is designed to “autocalibrate” on a continuous basis. It calculates SV using a general equation: \( SV = K \times \text{pulsatility} \), where \( K \) is a constant including arterial compliance and vascular resistance [63]. This constant is initially derived by patient variables such as height, weight, sex, and age using a method described by Langewouters and colleagues [64] and is subsequently adjusted once per minute using arterial waveform characteristics. Pulsatility is determined by analyzing the standard deviation of the arterial pressure waveform over preceding 20-second intervals. Thus, the variables used to calculate SV are updated at least once per minute. This algorithm offers the advantage of not needing an
alternative method for calculating CO for calibration purposes. When compared to PAC thermodilution in a postcardiac surgery setting, this system showed good correlation over a wide range of COs. Additionally, it appears that a radial artery catheter is just as accurate as a femoral artery catheter in this setting, which is another advantage of this system [63]. However, autocalibrated CO measurements have been shown to be inaccurate in hyperdynamic and vasodilated states, such as sepsis or after liver transplantation [65,66]. Thus, Edwards has worked to upgrade its algorithm in order to improve its accuracy across a broader range of physiologic conditions [67]. Although these modifications have been shown to improve the technology’s accuracy and ability to trend CO, they are met with mixed results, and the widespread applicability is still unsettled [68,69].

Clinical Utility

As mentioned above, the initial trials studying PCA systems used data from static ventricular loading conditions. Both the critically ill and intraoperative patients, however, often experience rapid changes in ventricular preload. The accuracy of the PiCCO system with dynamic changes of preload was addressed in a subsequent study, which used a modified algorithm. Felbinger and colleagues showed that changes in CO in response to preload could be accurately measured for a cardiac surgical ICU population when compared to pulmonary thermodilution [70].

While being able to monitor changes in CO during volume loading is important, being able to predict a priori when a patient would benefit from volume loading is perhaps more useful. Pulse pressures commonly vary throughout the respiratory cycle. Pulse pressure variation (PPV) is defined as the result of the minimum pulse pressure subtracted from the maximum pulse pressure divided by the mean of these two pressures.

\[
\text{PPV} = \frac{\text{Pulse Pressure}_{\text{max}} - \text{Pulse Pressure}_{\text{min}}}{\text{Pulse Pressure}_{\text{mean}}}
\]

The magnitude of the PPV in a patient can predict preload responsiveness [71–73] and has been shown to be more accurate than traditional static measurements of preload such as CVP or PAOP [74,75]. Analogous to PPV, an additional piece of data that PCA systems can provide is the stroke volume variation (SVV). The SVV represents the percent change in SV over time due to fluctuations in preload caused by respiration and is calculated using the same equation format as PPV (Fig. 28.2). A meta-analysis of PPV and SVV measured by PCA found that a PPV of 12.5% and SVV of 11.6% had moderate sensitivity and specificity when predicting a response to volume [76].
Figure 28.2 Stroke volume variation predicts volume responsiveness. The maximum and minimum stroke volumes during the respiratory cycle are calculated using a pulse contour analysis (PCA) system's algorithm. Larger variations in stroke volume predict volume responsiveness in the passively ventilated patient.

Due to these known limitations of the sensitivities and specificities of PPV and SVV to predict fluid responsiveness, some investigators have begun to examine the utility of using a range of PPV and SVV cutoffs. Cannesson and colleagues studied this approach in 413 elective surgical patients. They found that a PPV of 9% or less provided 90% accuracy that a patient would not respond to volume loading whereas a PPV of 13% or greater predicted with 90% accuracy that someone would respond. Up to 24% of the patient population studied fell into the “gray zone” where PPV was between 9% and 13%. In the gray zone, the predictive accuracy of PPV is limited and the authors argue that the decision to volume challenge should be made on a case-by-case basis after analyzing the relative risks and benefits [77]. This pragmatic approach to hemodynamic management has inherent appeal and could easily be applied to other modalities.

An important difference between PCA systems which have the ability to perform transpulmonary thermodilution (PiCCO, VolumeView) and those that do not (FloTrac) is the ability of the thermodilution systems to provide volumetric estimates of preload. Through analysis of the thermodilution curve and the application of known mathematical relationships between intrathoracic volumes, these systems provide estimates of global end-diastolic volumes (GEDV) and extravascular lung water (ELW) [78,79]. Indexed values of GEDV may be used as an assessment of preload and is preferred over traditional measures such as CVP by some clinicians [80]. Additionally, elevations of indexed ELW have been associated with higher mortality rates and, thus, may provide prognostic data in the critically ill population [81]. Despite the addition of these volumetric data, there are little data at present to suggest whether
volumetric-based assessments of preload provide any clinical advantage to patient care compared with non-volumetric technology.

In fact, there are limited data to suggest that the use of PCA systems in the intensive care setting impacts clinically relevant outcomes [82]; however, their use in high-risk surgery has been associated with clinical benefit. In the OPTIMISE (Optimization of Cardiovascular Management to Improve Surgical Outcome) trial, 734 high-risk patients undergoing major gastrointestinal surgery were randomized to an uncalibrated PCA to guide CO optimization versus standard of care during surgery and up to 6 hours postoperatively. The trial showed a nonsignificant trend toward a reduction in a composite of postoperative complications including mortality. When the authors included the trial’s data in a meta-analysis, they found a 23% reduction in the postoperative complications and a trend toward reduced mortality [83].

Advantages and Disadvantages

Overall, the PCA system offers several advantages over the traditional “gold standard” of pulmonary artery thermodilution (Table 28.2). Depending on the system, only an arterial catheter (Flotrac) or an arterial catheter and a central venous catheter (PiCCO) are required, both of which are commonly in place in critically ill and higher risk surgical patients. Thus, unlike PACs, no additional invasive procedures are required to use these systems. The PCA systems also provide a continuous measurement of CO as opposed to the intermittent nature of traditional thermodilution systems. This approach not only facilitates faster response times to hemodynamic derangements but also saves the clinician the time required to perform repeat CO or volume responsive assessments as would be required with TTE. Finally, PCA systems require minimal to no training to interpret and, therefore, may be an ideal modality to use in a busy clinical setting.

As with any noninvasive method of monitoring hemodynamics, there are disadvantages to the PCA systems as well. Regardless of the system employed, their accuracy and precision in vasodilated states are still questioned in situations with extremes of SVR such as septic shock, liver transplantation, or vasopressor titration [68, 69, 84–86]. Further, it is critical for clinicians to recall that the use of SVV to predict fluid responsiveness using PCA systems has only been validated in passively mechanically ventilated patients, usually at tidal volumes >8 mL per kg [76]. Thus, the reliability of using SVV in the spontaneous breathing patients is unknown and likely limited. Another known limitation to the PCA systems is their inability to reliably predict volume responsiveness when currently recommended lung protective strategies (<6 mL per kg) are used [87]. Fortunately, this limitation may be diminished at higher PEEP levels and may also be circumvented by transiently increasing tidal volumes at the time of SVV measurement [88].

In addition to tidal volume, respiratory rate (RR) has also recently been shown to impact the association between SVV or PPV and volume responsiveness. On average, the transit time of blood through the pulmonary circulation is approximately three to four beats resulting in a slight delay in the impact of a positive pressure breath on SV. In theory, if the RR is high enough such that the ventilator is cycling between inspiration and expiration faster than the pulmonary transit time, PPV variation may become challenging to quantify. Indeed, De Backer et al. [89] demonstrated that when the HR to RR ratio was decreased to <3.6 in hypovolemic patients, PPV could no longer be detected. These findings suggest that PCA systems may have limited efficacy in volume status assessment for patients with severe ARDS who require high RRs in the setting of lung protective ventilation and high dead space fractions. Finally, because pulse pressure and SV are dependent upon preload which is proportional to diastolic filling time, arrhythmias such as atrial fibrillation which result in variable R-R intervals will generate large PPV and SVV which are independent of volume status. This concept limits the ability to use PCA systems in the presence of these common arrhythmias, although

catheter

Minimal training requirements

Disadvantages

- SVV inaccurate during low tidal volume ventilation and spontaneous breathing
- Questionable accuracy during low systemic vascular resistance states
- Questionable accuracy during vasoconstrictor use

ICU, intensive care unit; SVV, stroke volume variation
newer algorithms are making improvements in this regard [67].

Future Research

Future studies that may help in defining the clinical role of PCA systems could focus on several points. First, a better understanding of how changes in vascular tone and vasopressor use affect the accuracy of a particular system’s algorithm will help to determine if and when particular systems can be reliably used. Further exploration of the use of PCA systems to create clinical protocols akin to the previously described “gray zone” approach may help to reshape the ubiquitous clinical question, “Will this patient respond to fluids?” into the more patient-centered question, “Should I give this patient fluids?” Finally, examinations of how PCA systems could affect patient outcomes through tailored resuscitation protocols in sepsis and ARDS would further help to define their role in critical care.

Noninvasive Cardiac Output Monitoring (Bioreactance)

Background

The thoracic bioimpedance technique was first developed by Kubicek [90] as a means of noninvasively measuring the CO of astronauts. It involves the delivery of low amplitude, high frequency electrical current across the thorax. A series of sensing electrodes, which measure the change in voltage amplitude, are placed along the path of this current and can be used to calculate the electrical impedance intrinsic to the thorax. Because of the conductive properties of fluid, the thoracic bioimpedance is inversely proportional to the amount of fluid in the thorax at the time of measurement. Thus, as intrathoracic fluid volume increases during each cardiac cycle, the bioimpedance measured by the sensing electrodes decreases. This principle provides the basis for measuring the SV and, hence, CO using this technique. In order to estimate CO accurately, however, aortic blood flow must be distinguished from other sources of intrathoracic fluid movement. Simultaneously recording the electrocardiogram and using a computer algorithm to filter electrical noise caused by other fluid movement can accomplish this.

Investigations into the accuracy of bioimpedance have yielded mixed results. A large meta-analysis which compared CO measurement by thoracic bioimpedance and PAC thermodilution revealed a broad range of
correlation ranging from 0.44 to 0.75 [91]. A potential limitation which may impact the device’s accuracy is the electrical “noise” generated by extravascular fluid in the form of pulmonary edema and pleural effusions. Accordingly, a prior study in ventilated patients with acute lung injury demonstrated a poor correlation between CO measured by bioimpedance and PACs [92]. Further, data regarding the effects of obesity on the accuracy of bioimpedance measurements are inconsistent. Sageman and Amundson [93] found no correlation ($r^2 = 0.00$) between invasive cardiac index measurements and those measured by thoracic bioimpedance in a subset of obese patients post coronary bypass. In contrast, a retrospective review of a prospective database revealed that patients with a body mass index (BMI) greater than 30 kg per m$^2$ actually had equivalent correlation and less bias between thoracic bioimpedance and thermodilution when compared to patients with a BMI less than 30 kg per m$^2$ [94].

As suboptimal signal-to-noise ratios likely resulted in the substantial limitations of bioimpedance for these clinical scenarios, efforts have been made to improve the system’s accuracy. A newer modality known as bioreactance was developed which appears to offer reduction in electrical noise. Unlike bioimpedance which monitors changes in the voltage amplitude imparted by intrathoracic blood flow, the noninvasive cardiac output monitoring (NICOM) bioreactance system monitors the phase shift of electrical waves which occurs due to this flow [95]. Similar to bioimpedance, a set of electrodes are placed upon the chest which transmit alternating electrical current at a known frequency to a set of receiving electrodes. Additional sensing electrodes are placed in the path of the electrical current and transmit information regarding the current back to the NICOM system. Specifically, the sensing electrodes measure the amount of time delay or phase shift that occurs as the current travels across the thorax. Because alternating current is delayed by traveling through fluid, the measured phase shift is directly proportional to the amount of intrathoracic fluid present at any given moment. Thus, small fluctuations in phase shift can be detected between systole and diastole (Fig. 28.3) and can be extrapolated into a SV using proprietary algorithms. Further, changes in SV in response to volume expansion can be detected by comparing the phase shift before and after volume challenge allowing for an assessment of fluid responsiveness using this system.
Phase shift during the cardiac cycle using bioreactance. Noninvasive cardiac output monitoring (NICOM) detects phase shifts in electrical current during (A) diastole and (B) systole that are elicited by changes in intrathoracic blood volume. The measured phase shifts can be used to estimate stroke volume (SV), CO, and response to volume loading.

**Clinical Utility**

Since its inception, several studies have compared the accuracy of the CO measured by the NICOM bioreactance system to that measured by PACs or other minimally invasive modalities. Two early single-center studies demonstrated tight correlation between this system and PACs for both surgical and nonsurgical cardiac care unit patients [96,97]. This correlation was present during periods of stability and during periods of increasing or decreasing CO. Additionally, the bioreactance system detected changes in CO faster than traditional PAC monitoring. When compared to ED monitoring of an abdominal surgical population, there was substantial disagreement of absolute CO measurements; however, the modalities were concordant when assessing CO changes in response to volume loading [98].

As with other minimally invasive monitoring modalities, the ability of bioreactance to predict fluid responsiveness has also been examined. Unlike PCA or echocardiography assessment of inferior vena cava (IVC) diameter, bioreactance does not provide a respirophasic, dynamic measurement that can be determined without intervening on a patient. Instead, the phase shift is measured both before and after a fluid challenge and a ΔCO is calculated where any value ≥10% is considered fluid responsive. This approach requires that a fluid bolus be given and, therefore, may expose nonresponders to unnecessary volume before their
status can be established. In order to circumvent this shortcoming, investigators have begun to examine whether a ΔCO measured during a PLR can offer predictive capability without exposure to a fluid bolus. Benomar et al. [99] demonstrated that changes in CO during PLR correlated well with changes in CO after a 500-mL fluid challenge in a postcardiac surgery patient population using the bioreactance system. Tong and colleagues demonstrated similar findings in a small study examining bioreactance use in a septic population while simultaneously demonstrating that ΔCO during a PLR was a more accurate predictor of fluid responsiveness than SVV using a PCA system [100]. These same observations were also made for a heterogeneous critically ill population in which ΔCO during a PLR predicted fluid responsiveness with a 94% sensitivity and a 100% specificity [101].

The potential impact of thoracic bioreactance on clinical outcomes is still being determined. One early study examined the role of using the NICOM bioreactance system in trauma patients presenting to the ED. The authors report that CO derangements could be seen with a variety of clinical conditions including some in which hypotension was not present. Further, the length of stay during the study was significantly shorter in a subset of patients with injury severity scores ≥ 15 as compared to a similar cohort over two preceding years [102]. Lee et al. [103] also examined the impact of bioreactance monitoring on length of stay in a small cohort of patients undergoing valvular heart surgery. While they found no significant difference in length of stay with its use, they did discover that patients who received bioreactance monitoring experienced lower rates of both epinephrine use and prolonged mechanical ventilation. At present, additional studies examining the clinical benefits of this technology are lacking.

**Advantages and Disadvantages**

Perhaps the biggest advantage of the bioreactance monitoring system is its truly noninvasive nature (Table 28.3). Unlike PCA or ED, this system has no invasive components similar to TTE. Unlike TTE, however, bioreactance monitoring has the additional advantage of providing CO measurement on a near-continuous basis. The system displays the average CO over a preceding 1-minute interval which allows it to display accurate, real-time information without dramatic fluctuations from transient artifactual readings. Thus, the system allows for early detection of derangements akin to PCA and ED while remaining completely noninvasive. Another advantage of the bioreactance system is its compatibility with arrhythmias. Whereas minimally invasive modalities such as PCA are confounded by the impact that irregular diastolic filling times have on the beat-to-beat variation in SV, the bioreactance system
has been shown to function reliably in the setting of atrial fibrillation [103]. Finally, patient positioning, and the need for frequent repositioning do not affect the accuracy of the bioreactance system offering a potential advantage over ED monitoring which can require adjustment each time a patient is moved [98].

| Concept: External thoracic electrodes estimate stroke volume by monitoring the phase shift of current applied to the chest wall |
| Advantages |
| Completely noninvasive |
| Provides continuous measurements of CO |
| Accurate with atrial fibrillation |
| Not affected by patient positioning/repositioning |
| Disadvantages |
| Ability to predict volume responsiveness without volume challenge is limited |
| Limited accuracy during upper abdominal surgery |
| Impact of electrical cardiac pacing not completely characterized |

As with all minimally invasive monitoring systems, there are potential disadvantages to the NICOM bioreactance system as well. First, as described above, the system is unable to predict fluid responsiveness without: (a) giving a fluid challenge or (b) performing a PLR maneuver. As 40% to 60% of patients in shock are not fluid responsive, the first approach may lead to frequent administration of unnecessary fluid [104,105]. Because the NICOM displays CO representative of an average value over the preceding minute, there is a brief delay before the response to a PLR would be observed. As data suggest that the effects of a PLR can disappear after 1 minute, it is possible that augmentations of CO from the PLR maneuver may be underestimated by bioreactance [35]. This may explain some of the mixed results about its efficacy at predicting volume responsiveness using this approach [101,106]. An additional disadvantage of the bioreactance system is its inability to accurately measure CO in certain clinical scenarios. Most notably, the system has been shown to
perform poorly during upper abdominal surgery likely due to alterations in torso geometry, which can affect the derivation of SV from phase shift data [107]. This same limitation was again noted during liver transplantation but has not been seen in surgeries on the lower abdomen [107,108]. Finally, as the bioreactance system is based upon the measurement and analysis of electrical current, the introduction of extrinsic electrical signals may confound its accuracy. Accordingly, intraoperative electrical cautery has been shown to distort the signals of the bioreactance system and affect its accuracy [98]. The impact of implantable cardiac pacing devices on the system’s accuracy is not fully known as interference has been reported but at least one study reports adequate performance during pacing [96,109].
The thoracic bioreactance technology demonstrates considerable promise as a noninvasive means of monitoring CO and has supplanted bioimpedance due to its superior signal-to-noise capture. However, many questions regarding the clinical benefit of this technology remain. Although previous studies have investigated the accuracy of this system for hemodynamically unstable patients, the proportion of subjects who had pulmonary edema was either zero or not reported in these studies [96,101]. As pulmonary edema was a known confounder of the bioimpedance system, more data regarding its effect on the performance of the bioreactance system are necessary before this system can be broadly recommended. Further clarification of the system’s ability to predict fluid responsiveness during a PLR maneuver is also important and should be performed with careful attention to the PLR protocol to avoid confounding [110]. Finally, as with most minimally invasive monitoring technologies, data regarding this technology’s impact on clinical outcomes such as mortality, organ failure, length of stay, and cost are currently lacking. Only once these data are available can definitive practice recommendations be made.
OXYGEN DELIVERY AND TISSUE PERFUSION

While directly measuring CO can provide information vital to the management of critically ill patients, one can also argue that accurate knowledge of oxygen delivery and/or adequacy of tissue perfusion can be similarly useful. Proponents of this concept are less interested in the absolute CO as long as tissue oxygenation is adequate. Commonly used indirect measurements of oxygen delivery are central venous oxygen saturation ($S_{cv}O_2$) and lactate. Alternative modalities for measuring tissue perfusion are gastric tonometry and sublingual capnometry, which measure the concentration of $CO_2$ at the tissue level as a surrogate for tissue perfusion [111,112]. While some early studies found gastric tonometry-based protocolized resuscitation strategies to be of clinical benefit [113,114], others have not [115–117]. Although conceptually appealing, gastric tonometry and sublingual capnometry have failed to gain widespread popularity and, thus, will not be discussed further here.

$S_{cv}O_2$

Background

$S_{cv}O_2$ is an indirect measure of the oxygen content returning from the upper body through a properly placed central venous line in the superior vena cava (SVC). It is reflective of the balance between systemic oxygen delivery ($DO_2$) and systemic oxygen consumption ($VO_2$).

Conceptually, as CO (and $DO_2$) decrease, tissue extraction of oxygen will undergo a compensatory increase in order to sustain $VO_2$ leading to a reduction in $S_{cv}O_2$. Thus, monitoring $S_{cv}O_2$ can provide useful information regarding the adequacy of CO over time.

The $S_{cv}O_2$ is analogous to the mixed venous oxygen saturation ($S_{v}O_2$), which is used less frequently in noncardiac ICUs as it requires a PAC. As $S_{v}O_2$ is considered to be a more exact measurement of global body oxygen delivery, several studies have examined the relationship of the two variables in order to determine the utility of $S_{cv}O_2$. An early study in healthy humans found that $S_{cv}O_2$ tended to be approximately 5% to 10% lower than $S_{v}O_2$ likely related to insufficient mixing of blood from the
SVC, IVC, and coronary sinus in the right atrium [118]. However, more recent data suggest that in the setting of critical illness or surgery, the relationship between $S_{cv}O_2$ and $S_vO_2$ reverses with the former having larger values possibly caused by alterations in regional perfusion related to these conditions [119–121]. Regardless of the cause, these data have raised the question of whether $S_{cv}O_2$ is truly an appropriate surrogate marker of systemic oxygen delivery. In support of its adequacy, Reinhart et al. found a very good correlation ($r = 0.81$) between $S_{cv}O_2$ and $S_vO_2$ in a heterogeneous population of high-risk surgical and medically ill patients. In addition, the authors observed that changes in $S_vO_2$ led to proportionate changes in $S_{cv}O_2$ in both direction and magnitude over 90% of the time [119]. In contrast, numerous studies have demonstrated a relatively poor correlation between the two values in the setting of anesthesia or circulatory failure, particularly when $S_vO_2$ is <70% [121–124]. In these studies, the oxygen extraction ratio was repeatedly identified as a predictor of poor correlation. Intriguingly, one study demonstrated that a large discrepancy between $S_vO_2$ and $S_{cv}O_2$ was an independent risk factor for postoperative complications suggesting that the discrepancy is both real and may have clinical ramifications [125].

Despite the apparent controversy surrounding the accuracy of $S_{cv}O_2$ as a measure of oxygen delivery, much focus has been given to studying its use as a prognostic marker. As many as 60% of patients admitted with septic shock in the absence of preexisting heart disease experience myocardial dysfunction in the setting of their acute illness [126]. A prospective study of this population demonstrated that a $S_{cv}O_2$ cutoff of <64% predicted a reduced cardiac index with high positive and negative predictive values [127]. Supranormal $S_{cv}O_2$ levels, however, can also be associated with impaired oxygen delivery if the tissues have suffered significant damage and are unable to extract oxygen effectively in the setting of mitochondrial failure [128]. In fact, both low and elevated $S_{cv}O_2$ levels have been associated with increased mortality rates of patients admitted with sepsis [129,130].

Clinical Utility

Due to its minimally invasive nature and the development of catheters which allow for continuous measurement, $S_{cv}O_2$ has been used as a protocolized resuscitation target with mixed success. In an early landmark single-center trial, Rivers et al. demonstrated a significant reduction in mortality among patients with septic shock who were treated with an early and aggressive protocolized resuscitation which included
interventions to target a $S_{cv}O_2 \geq 70\%$ [50]. These data were counter to an earlier study which had targeted normal $S_vO_2$ levels in a similar population [131] and were felt by many to be related to the early nature of the intervention. However, recent multicenter studies designed to validate the utility of early protocolized management of oxygen delivery using $S_{cv}O_2$ measurement have failed to demonstrate its benefit over the current standard of care [132–134]. The Protocolized Care for Early Septic Shock study (ProCESS) randomized patients into three arms: (1) an early goal-directed therapy (EGDT) arm whose care mimicked that of the original Rivers’ study; (2) a protocolized resuscitation arm based on clinical assessment which did not require the use of a central venous catheter or the measurement of $S_{cv}O_2$; and (3) a usual care group in which all interventions were left to the clinical care team. Despite more dobutamine use and blood product administration in the EGDT arm, there was no mortality difference in the three treatment arms, while overall mortality was lower than predicted at 19% [132]. Similarly, the Australian Resuscitation in Sepsis Evaluation (ARISE) study enrolled 1,600 subjects to EGDT vs. usual care, and also found no difference in all-cause 90-day mortality (18%) despite a high level of adherence to the EGDT protocol [133]. Finally, the Protocolised Management in Sepsis (ProMISe) trial randomized 1,260 subjects with septic shock to EGDT versus usual care. Once again, resuscitation protocols incorporating $S_{cv}O_2$ as a surrogate end point provided no mortality benefit, however, did result in longer ICU stays and modest increases in cost [134].

At present, it is not clear why protocolized targeting of $S_{cv}O_2$ does not improve outcomes in septic shock. Possibilities include its known limitation for accurately reflecting oxygen delivery in those with circulatory failure as well as a heightened awareness that the standard of care for sepsis management should include early and aggressive resuscitation. Regardless, the utility of targeting $S_{cv}O_2$ in distributive shock appears to be limited at present. However, its use in guiding inotropic therapy for cardiogenic shock is still highly prevalent and may also have a role in perioperative care where it has been shown to be associated with reductions in length of stay and postoperative complications [135].

Lactate

Background

The physiologic basis for lactate production is a shift from mitochondrial oxidative phosphorylation to anaerobic glycolysis during times of
circulatory failure or tissue hypoxia. Elevated lactate levels have been repeatedly associated with worse outcomes among critically ill patients [136–138]. This association is present even when clinical signs of macrocirculatory failure are absent and after adjustment for other confounding factors such as age and organ failure [139,140]. As such, investigators have been interested in exploring the prognostic capabilities of lactate as well as its utility as a resuscitation target.

Bakker et al. [136] noted that in addition to higher initial levels of lactate, non-survivors of septic shock also failed to clear lactate from their bloodstream. Subsequently, Nguyen and colleagues prospectively evaluated if early change in lactate levels, termed “lactate clearance,” was a clinically useful indicator of survival in patients with suspected severe sepsis:

\[
\text{Lactate Clearance} = \left( \frac{\text{Lactate}^{\text{ED presentation}} - \text{Lactate}^{\text{Hour 6}}}{\text{Lactate}^{\text{ED presentation}}} \right) \times 100
\]

They found that survivors had a significantly higher rate of lactate clearance (38.1% vs. 12%) at hour 6 and that for each 10% increase in lactate clearance, mortality decreased by 11% in a multivariate analysis [141]. A similar association between lactate clearance and survival has also been seen in trauma and burn populations [137,138], and lactate clearance has also been associated with improved neurologic outcomes after cardiac arrest [142].

**Clinical Utility**

When compared to targeting \( S_{cv}O_2 \) levels for septic shock, targeting lactate clearance appears to be more efficacious. This was suggested initially in retrospective studies which analyzed outcomes from a prospective trial of sepsis resuscitation in emergency departments. The authors observed that patients who did not successfully clear lactate had high mortality rates despite the fact that the majority of these patients had achieved a \( S_{cv}O_2 \geq 70\% \) [143]. In a follow-up study, they demonstrated that achieving a lactate clearance of at least 10% in the absence of achieving a \( S_{cv}O_2 \geq 70\% \) was associated with a fivefold reduction in mortality as compared to achieving a \( S_{cv}O_2 \geq 70\% \) but failing to achieve lactate clearance [144]. These findings have been further substantiated by a recent meta-analysis which demonstrated that lactate
clearance is associated with survival among critically ill patients [145].

In light of the association between lactate clearance and improved outcomes, Jansen et al. [146] investigated whether specific lactate-guided treatment protocols in the first 8 hours of ICU admission improves outcomes over standard of care for patients admitted with hyperlactemia. They prospectively randomized critically ill patients with a serum lactate ≥ 3 mEq per L on presentation to an intervention arm whose therapeutic goal was a 20% clearance in lactate every 2 hours or to a usual care arm. Although there was no significant difference in lactate levels between the two groups, the lactate-guided arm accomplished faster weaning from mechanical ventilation, shorter ICU stays, and reduced adjusted in-hospital mortality [146]. Finally, protocolized therapy targeting lactate clearance has also been compared head-to-head with protocolized targeting of $S_{cv}\text{O}_2$. In a multicenter non-inferiority randomized controlled trial, septic patients were randomized to receive early resuscitation using either $S_{cv}\text{O}_2$ or lactate clearance as an end point of oxygen delivery. In-hospital mortality rates were 17% in the lactate-guided group and 23% in the $S_{cv}\text{O}_2$ group and met the criteria for non-inferiority [147].

Advantages and Disadvantages

There are several theoretical advantages to blood markers of tissue perfusion such as $S_{cv}\text{O}_2$ and lactate (Table 28.4). Because they are indicators of the adequacy of tissue perfusion rather than a measurement of actual CO, they may be a more clinically appropriate method of guiding hemodynamic management. Although $S_{cv}\text{O}_2$ measurement requires a central venous catheter placed either in the internal jugular vein or in the subclavian vein, many patients who require close monitoring of oxygen delivery already have such central venous access. Thus, $S_{cv}\text{O}_2$ measurement does not increase the invasiveness of care in most patients. In addition, point of care measurement of $S_{cv}\text{O}_2$ is rapid and relatively inexpensive. The development of continuous $S_{cv}\text{O}_2$ monitoring catheters further improves the ability to monitor oxygen delivery in a convenient and real-time fashion [67], although it does represent an increase in the cost of care. Similarly, lactate measurement is also fast and affordable and has the added advantage of not requiring a central venous catheter. Finally, the accumulating evidence that lactate clearance is associated with clinical outcomes, including mortality, suggests that its monitoring may provide valuable clinical data [143–145].

| TABLE 28.4 Advantages and Disadvantages of... |
Markers of Perfusion and Tissue Oxygenation Method for Cardiac Output Monitoring

Concept: Using lactate and $S_{cv}O_2$ as surrogate markers for adequate supply (CO) for a given metabolic demand

Advantages
- Utilizes catheters that are already commonly used in ICU
- No upfront capital investment
- Readily available, inexpensive tests
- Lactate clearance linked to clinical outcomes
- Representative of cellular function
- Potentially continuous

Disadvantages
- $S_{cv}O_2$
  - Not associated with clinical outcomes
  - Accuracy is position dependent
  - Levels above goal may represent ongoing tissue ischemia
- Lactate
  - Falsely elevated due to:
    - Aerobic production
    - Impaired clearance
    - Not continuous

CO, cardiac output; ICU, intensive care unit; $S_{cv}O_2$, central venous oxygen saturation.

There are limitations to the use of $S_{cv}O_2$ and lactate as well. First, while derangements in each value can identify the presence of inadequate oxygen delivery, neither will provide information regarding the underlying etiology of the derangement. Thus, their use may still require additional diagnostic testing in addition to clinical acumen. Additionally, the accuracy of $S_{cv}O_2$ measurements is dependent upon the position of the central venous catheter. Femoral catheters only provide evidence of oxygen delivery and extraction to the lower extremities and, thus, are not useful for assessment of vital organs. As outlined above, catheters placed in the internal jugular and subclavian veins may also provide inadequate representations of global oxygen delivery, particularly in the setting of circulatory failure [121–124]. The accuracy of $S_{cv}O_2$ levels may improve if the catheter tip is positioned in the right atrium [148]; however, the appropriateness and safety of such positioning is debated [149]. A further
limitation is the fact that elevated levels of $S_{cv}O_2$ are not always indicative of adequate tissue oxygenation but, instead, may occur in the setting of mitochondrial failure when ischemic tissue loses the ability to extract oxygen effectively. As such, the clinician must not be falsely reassured by normal or supranormal values when other clinical clues suggest ongoing shock. Finally, and most importantly, accumulating evidence suggests that $S_{cv}O_2$-targeted therapy does not impact relevant clinical outcomes calling into question the appropriateness of its use in specific diagnoses such as septic shock [132–134].

The use of lactate and its clearance as surrogates for ongoing tissue hypoxia and anaerobic metabolism also have some limitations. There is evidence to suggest that hyperlactemia can result from aerobic glycolysis of well oxygenated tissues. One explanation for this finding is that epinephrine-induced activity of skeletal muscle Na$^+–$K$^+$ ATPase leads to hyperlactemia [150,151]. In times of stress, such as sepsis, endogenous and exogenous levels of epinephrine rise which can increase detectable levels of lactate despite adequate tissue perfusion [150]. Similarly, impairment of lactate clearance can also confound lactate levels in critically ill patients. Liver dysfunction and sepsis-related alterations in pyruvate dehydrogenase activity have both been associated with impaired lactate clearance and increased blood lactate levels [152,153], and higher baseline lactate levels have been associated with impaired clearance in a sepsis population [154].

**Future Research**

Although $S_{cv}O_2$-guided protocolized care does not appear to impact clinical outcomes from sepsis, the clinical utility of lactate-guided protocols is still being determined. Further examination of strategies using lactate clearance as a resuscitation end point will likely be forthcoming and informative of this measure’s therapeutic potential. Alternatively, in light of the strong association between lactate clearance and survival, lactate levels may also find a role as a surrogate end point for other interventions over time. Finally, future research into the capabilities of markers of tissue perfusion to predict which patients are likely to experience complications early in the course of presentation may help to better triage patients and facilitate rapid interventions for patients with occult shock.
Independent of which hemodynamic monitoring technique is employed, a strategy that should be utilized for all patients with shock is early intervention aimed at restoring organ perfusion (Table 28.5). Mounting evidence suggests that mitochondrial failure may play a role in late shock \[128\] and efforts to correct hemodynamic derangements early in shock have shown promising results \[50\]. However, the accumulation of data suggesting that protocolized targeting of \(S_{cv}\text{O}_2\) does not improve outcomes in sepsis argues that focus on oxygen delivery may not be a crucial component to an interventional approach so long as volume resuscitation and pressor support are supplied early \[132–134\].

\(S_{cv}\text{O}_2\): central venous oxygen saturation.

The optimal method for hemodynamic monitoring is yet to be determined. Although pulmonary artery thermodilution remains the “gold standard” for measuring CO, its use continues to decline among noncardiac critically ill patients. ED offers the benefits of continuous monitoring, low infectious risk, and relative ease in placement. Its use during major surgery has been associated with earlier tolerance of oral nutrition and shorter lengths of stay; thus, its use can be recommended in this clinical setting. Similarly, PCA-guided optimization of CO during high-risk abdominal surgery has also been associated with reduced postoperative complications and its use is also recommended.

A common finding in nearly all studies of minimally invasive
hemodynamic monitoring modalities is that dynamic measures of fluid responsiveness are superior to traditionally used static measurements such as CVP or PAOP. Accordingly, the authors recommend that regardless of which minimally invasive monitoring modality is used, clinical decision-making regarding volume resuscitation can be aided by dynamic measurements such as PPV, SVV, or ΔVTI. However, before clinical decisions are made based on these techniques, it is imperative that clinicians who use them understand the limitations of each measurement and the clinical situations in which they can and cannot be accurately used.

Finally, the role of lactate and its clearance for the management of shock is still to be determined. Although lactate clearance has been shown to be non-inferior to $S_{cv}O_2$ as a resuscitation end point, the utility of $S_{cv}O_2$ targeting is now in question [147]. Further studies may allow for more definitive recommendations regarding its use as a resuscitation guide in the future.
As medical technology continues to advance at an explosive rate, it is easy to imagine that ICU practice will change in the not too distant future. The next generation of intensivists and likely younger members of this generation may find themselves looking back with awe at the “archaic” methods of current practice. In particular, the widespread application of high throughput proteomic and transcriptomic analyses to patients with shock has great potential to unlock new noninvasive biomarkers that may aid in both the prognosis and hemodynamic management of these patients.

Genome-wide association studies and predictive modeling have identified candidate genes and their associated proteins that have been associated with increased mortality in septic shock [155]. When tested in an adult population, a signature of five plasma proteins combined with age, lactate, and chronic illness burden were found to have superior predictive accuracy to the widely used APACHE II score [156]. The investigators went on to examine quantitative expression levels of messenger RNA in a larger previously identified group of 100 genes. They demonstrated that the expression patterns of this combinatorial signature could successfully classify children with sepsis into different subclasses, and that subclass designation was associated with organ failure, mortality [157], and the response to steroid therapy [158]. Importantly, using the investigators’ methodology, patients could be subclassified within 12 hours raising the possibility of real-world clinical applicability. Thus, proteomic and genomic analyses may be finally approaching the era of rapid turnaround personalized medicine. Similar discoveries in the future could potentially influence a wide variety of hemodynamic management decisions including volume status management and pressor choice.

Echocardiography as a Monitor in the ICU

ACHIKAM OREN-GRINBERG • TODD W. SARGE • ADAM B. LERNER

INTRODUCTION

The past decade of patient care can easily be described as the ultrasound revolution. Improvement of ultrasound technology allowed for miniaturization of equipment and reduced costs, allowing this technology to find its way into all corners of patient care. The concept of “point-of-care (POC) ultrasound” was born and has dominated the bedside patient evaluation in many areas. Today, clinicians all over the world depend on ultrasound machines to manage critically ill patients. Ultrasound is used for diagnosis (e.g., cardiac disease, lung pathology peritoneal fluid and bleeding, deep vein thrombosis [DVT], etc.) and for procedures (e.g., vascular access, thoracentesis, paracentesis, etc.).

Many clinicians quickly adopted echocardiography, and the more focused form of it—focused cardiac ultrasound—as a diagnostic tool for their patients. Echocardiography provides both anatomic and functional information about the heart. The relative ease of use, rapid retrieval of information along with low complication rates, has all led to adaptation of echocardiography to the critical care environment. Nevertheless, the revolution is still ongoing—graduated clinicians continue to pursue education about this new modality, and student doctors learn focused cardiac ultrasound as part of new POC ultrasound curricula at many medical schools.

With growing experience and knowledge managing patients with this new modality, echocardiography is now used by critical care physicians not only for initial diagnosis but also as a form of monitoring. This paradigm shift challenges the traditional way of “doing business” with
regard to hemodynamic monitoring. Although there is still no clear-cut evidence of its benefits, echocardiography is well received by clinicians, maybe because “seeing is believing.” Clinicians can now perform cardiac ultrasound at the bedside and quickly determine the cause of hemodynamic derangement. However, patient safety and optimal outcome depend heavily on a thorough understanding of both the strengths and limitations of the available technologies and their applications. This chapter concentrates on the use of echocardiography in the intensive care unit (ICU) with an emphasis on its role as a hemodynamic monitor.
LIMITATIONS OF HEMODYNAMIC MONITORS

Hemodynamic monitors play an essential role in the management of critically ill patients. The pulmonary artery catheter (PAC) that was introduced in the early 1970s [1] changed the care of critically ill patients by allowing clinicians to measure extensive hemodynamic variables, such as cardiac output (CO), cardiac filling pressures, and global oxygen transport, at the patient’s bedside. For many years, the PAC was considered the standard of care in critical care. However, formal studies on the impact of the PAC have documented increased mortality and increased utilization of resources with the use of the PAC [2]. While several large randomized controlled trials could not confirm these findings, they also failed to demonstrate improved outcomes when patients were managed using the PAC [3–6]. These and other publications led to a significant decline in utilization of PAC over the ensuing years [7,8].

The void of hemodynamic monitoring was quickly filled with “new” hemodynamic monitors, usually less invasive and some considered completely noninvasive. Although most of these monitors were evaluated by both experimental and clinical studies, to-date, no specific monitoring device has been found to reduce mortality for critically ill patients [9]. The reality is that no hemodynamic monitoring technique can improve outcomes by itself. Rather, outcomes can only improve if the following three conditions are met: (1) the technique provides accurate data; (2) the data obtained is relevant to patient management; and (3) significant management changes are made based on the data obtained [10]. It is also important that the data is interpreted and applied correctly and that the applied therapies are not ineffective or harmful [10].

One major advantage echocardiography has over many other hemodynamic monitors is that it provides crucial diagnostic information during the vital moments of the first patient encounter and at the time of hemodynamic instability. It can then be used for monitoring key hemodynamic parameters (e.g., CO, PA pressure, etc.) after application of therapies or their adjustment in a paradigm that optimizes hemodynamic responses.
ECHOCARDIOGRAPHY AS A
HEMODYNAMIC MONITOR

Until recently, echocardiography has been considered as a useful diagnostic modality and was not regarded as a hemodynamic monitoring technique. This concept is changing with the fast growing field of POC ultrasound [11]. POC ultrasound—ultrasonography performed and interpreted by the clinician at the bedside—allows clinicians to gain experience with using comprehensive echocardiography as well as focused cardiac ultrasound for the management of critically ill patients. The growing use of ultrasound and specifically cardiac ultrasound for the management of critically ill patients leads to a paradigm shift with regard to hemodynamic monitoring. Thus, it is not surprising that with this growing change of practice, current guidelines recommend using cardiac ultrasound to monitor therapeutic responses of critically ill patients [12,13].

Although echocardiography has many advantages, both as a diagnostic tool and as a monitoring technology, it is important to understand how its use differs from the more traditional hemodynamic monitoring. First, unlike most hemodynamic monitors that provide data continuously, echocardiography provides information only intermittently. The exception is when transesophageal echocardiography (TEE) is used in periods of hemodynamically instability, where it can provide continuous information for as long as the TEE probe is left in position and a qualified clinician is there for interpretation of the images. Despite this limitation, there is no proven advantage to continuous over intermittent monitoring. Second, echocardiography requires considerable initial and continuing education whereas, typically, there are no such requirements for the use of other hemodynamic monitors. Although this could be perceived as an advantage for traditional hemodynamic monitors, a relative lack of knowledge without continuing education may provide the clinician with an incorrect understanding of a patient’s hemodynamic status. Lastly, echocardiography may be not useful for some patients owing to poor image quality. Reasons for poor image quality include body habitus (either high [14] or low body mass index [15]), patient’s comorbidities (e.g., chronic obstructive pulmonary disease [COPD]), mechanical ventilation, high positive end-expiratory pressure, surgical dressings, chest tubes and drains, poor positioning, operator experience, and machine quality.
COMPARISON BETWEEN TRANSTHORACIC ECHOCARDIOGRAPHY AND TRANSESOPHAGEAL ECHOCARDIOGRAPHY IN THE ICU

Although both transthoracic echocardiography (TTE) and TEE are used by intensivists for the management of critically ill patients, TTE use is more widespread. Each modality has its advantages and disadvantages with regard to image quality, cardiac anatomy obtained, and logistics. Understanding the similarities, differences, and benefits of the two modalities can be useful for the intensivist.

Whereas TEE generally provides superior image quality compared to TTE, anterior structures such as the right ventricle (RV), right ventricular outflow tract (RVOT), pulmonic valve, and anterior pericardium can be better imaged by TTE. In addition, the apical TTE views provide better imaging of the left ventricular apex. Posterior structures such as the left atrium; mitral valve and subvalvular apparatus; and interatrial septum and left atrial (LA) appendage are best imaged with TEE [16]. TEE is also better than TTE for evaluating patients for a potential source of cerebral embolus [17].

TEE is somewhat invasive and, although rare, has been associated with complications, some of which may be significant [18–20]. TTE, on the other hand, is noninvasive and outside misinterpretation, is practically risk free. Logistically, TEE is more costly and challenging to maintain because it requires cleaning and disinfection after each use in a dedicated disinfecting apparatus. It also requires special storage and handling and is limited to use in one patient at a time with a few hours of cleaning time in between patients. This limits the number of patients that one TEE probe can service in a single day. In contrast, TTE can be rapidly disinfected and used repeatedly on the same or different patients and can be used anywhere in the hospital (e.g., during resuscitations on the wards) and even at prehospital settings. TEE performed by noncardiologists is usually limited to the perioperative environment, ICU [21], and the emergency department [22].
CARDIAC OUTPUT

Introduction

CO is a critical factor affecting global oxygen transport to tissues and organs. Although there are no absolute values that reflect adequate circulation for an individual patient, most clinicians agree that very low values (e.g., CI < 2.0 L per m²) are associated with worse outcomes. Thus, it is reasonable to monitor CO in critical illness to assess for impairments of cardiac function with the goal of normalization as is feasible.

Current CO techniques include (1) thermodilution (either the transpulmonary technique or intracardiac technique using the PAC); (2) arterial pulse contour analysis; (3) noninvasive bioreactance; (4) Doppler technologies measuring blood flow in the ascending or descending aorta; (5) partial CO₂ rebreathing technique (using the modified Fick equation); and (6) arteriovenous oxygen content differences using the Fick equation (that also requires a PAC). Each of these techniques and methods has strengths and limitations that should be considered when choosing a method to evaluate an individual patient.

Echocardiographic Measurement Technique

CO can be measured relatively easily and quickly with echocardiography, and can be integrated into the clinician’s assessment of critically ill patients [23]. In contrast to many hemodynamic monitors, CO measurement with echocardiography is not continuous and requires the clinician to be at the patient’s bedside. It can be repeated as needed to monitor response to therapies (e.g., volume expansion therapy or initiation of inotropes).

Although there are several echocardiographic techniques that can be used to measure CO, most clinicians use a continuity-based assessment of flow in the left ventricular outflow tract (LVOT). In this technique, the LVOT is assumed to have a cylindrical shape and its cross section estimated by a circle. Because the volume of a cylinder is calculated by multiplying its cross-sectional area (CSA) with its height, one can see that the same calculations can be applied to the volume of the LVOT, resulting in calculation of a patient’s stroke volume (SV).

The circular CSA of a cylinder is calculated by the formula πr². To
calculate the CSA of the LVOT with TTE, the parasternal long-axis (PLAX) view (Video 29.1) is used to measure the LVOT diameter, from which the computer computes the radius. A key to success is optimizing the image quality and then zooming in on the LVOT before measuring its diameter (Video 29.1). This will improve accuracy and minimize measurement error because any error of the diameter/radius measurement will be squared. It is best to standardize the point of measurement of LVOT diameter, and many clinicians choose the point of aortic valve leaflet attachment to the LVOT (aortic valve annulus) as the measurement point.

To calculate the height of the cylinder, usually the apical 5-chamber (A5CH) view is used (Video 29.1), but if the quality of this view is suboptimal, the apical 3-chamber (A3CH) view can also be used, provided its angle of interrogation is less than 20 degrees off the flow of blood (Video 29.1). Blood flow velocity through the LVOT is measured with pulse wave Doppler, ideally at the same point where the diameter was measured (at the level of the aortic annulus). A characteristic spectral display is generated, where each wave represents velocity over time of one SV. By tracing one of these curves, the computer calculates the velocity time integral (VTI), which is the area under the curve. Conceptually, this is the average displacement (i.e., distance) of the column of blood that moved through the LVOT in the measured wave. This “stroke distance” is the height of the cylinder in centimeters that is used to complete the calculation of the LVOT cylinder SV.

Multiplying the LVOT cylinder’s CSA (cm²) with its height (cm) produces one SV (cm³ or mL). The computer then calculates CO by multiplying SV with the heart rate.

If TEE is used, the midesophageal long-axis view is used to measure the LVOT diameter (Video 29.1), and the VTI is measured in the deep transgastric view (Video 29.1).

**Stroke Volume Estimation**

For critically ill patients, close attention should be made to SV because it can provide important information on the patient’s hemodynamic state. For example, a patient with CO of 5 L per minute and heart rate of 60 beats per minute has normal SV of 83 mL per minute. In contrast, the SV of a different patient with the same CO and heart rate of 125 beats per minute is only 40 mL per minute, which is likely to be pathologic.

Therefore, SV can be monitored serially to assess improvement after initiation of therapy. Critically ill patients often have difficult windows yielding suboptimal image quality. For example, a patient with a difficult PLAX view may prohibit the accurate measurement of the LVOT diameter. In such patients, the velocity time index (VTI), which is a
reflection of SV, can be followed serially. As the LVOT is an anatomic structure, its diameter and, thus, the CSA do not change significantly with therapies. Thus, in reality, it is the VTI and changes to the VTI that are more critical for monitoring a patient’s CO and hemodynamic responses to therapies. On average, a normal VTI is greater than 18 cm that corresponds to an SV of roughly 60 mL (low normal SV). Serially following the VTI can help guide the clinician toward success for optimizing a hemodynamic therapeutic intervention [24].

Pitfalls and Limitations of Cardiac Output Measurement

Left Ventricular Outflow Tract Diameter Measurement

Because any error in the measurement of the LVOT diameter will be squared in the CO calculation, it is important to generate quality PLAX view, zoom on the LVOT, and measure it meticulously. Averaging several measurements of LVOT diameter will reduce the measurement error.

Doppler Measurement of Velocity Time Integral

The measured Doppler velocity is a function of the cosine of the angle between blood flow and the ultrasound beam. Therefore, accurate VTI measurement occurs when the Doppler beam is parallel to blood flow, and care should be taken to ensure that the Doppler beam is parallel to the LVOT when making this measurement. An angle of less than 20 degrees is desirable to maintain an error of less than 6%. Similar to LVOT measurement, averaging several VTI measurements will reduce its measurement error.

Arrhythmias

Arrhythmias (e.g., atrial fibrillation) often lead to beat-to-beat variation in SV and VTI. To improve accuracy, several VTIs should be measured and averaged to better gauge SV, particularly in the setting of irregular heart rhythms.
FLUID MANAGEMENT

Introduction

Early and adequate resuscitation is an important determinant of outcome for many critically ill patients. For example, among septic patients, early resuscitation is a part of the surviving sepsis bundle [25]. On the other hand, overly aggressive fluid administration has been linked to worsened outcomes and increased complications associated with lung physiology [26]. Therefore, determining an individual patient’s volume status and response to fluids has been one of the most challenging tasks for critical care professionals. Hemodynamic optimization of the critically ill patient requires the fine balance between preload, afterload, and myocardial contractility. Although echocardiography can help to some degree with understanding preload and fluid responsiveness, there are many limitations that must be taken into account when assessing the patient’s volume status. However, it should also be noted that this is true for all monitoring modalities with regard to fluid responsiveness. In this section, we discuss two aspects of volume status with case examples: (1) recognition of the patient with severe hypovolemia and (2) assessment of fluid responsiveness.

Severe Hypovolemia

Severe hypovolemia, the cause of hypovolemic shock, occurs with rapid and significant loss of blood volume or body fluid (e.g., diarrhea). If unrecognized and untreated, this life-threatening condition leads to inadequate organ perfusion and eventually death. Echocardiography can help for the diagnosis of severe hypovolemia and guide resuscitation.

The echocardiographic findings associated with severe hypovolemia include decreased dimensions of both the LV and RV cavities during systole and diastole, and a small inferior vena cava (IVC) diameter [13]. In addition, the IVC often collapses more than 50% with respiration. It is important to note that the IVC diameter is used not in isolation, but rather as part of a pattern to support a diagnosis of hypovolemia.

In the extreme situation of an “empty heart,” echocardiography can be very useful for following the response to aggressive fluid resuscitation. With volume loading, ventricular size is expected to increase, and serial examinations can document such effect of therapy.
However, assessment of severe hypovolemia may be more complex for patients with chronic heart disease. In this population of patients, dilatation of cardiac chambers can obscure associations between chamber size and assessments of preload. Therefore, a thorough patient history is extremely important, and no monitoring technology can substitute for this valuable information. For example, in the setting of chronically dilated LV, LA, right atrial (RA), or RV as well as left ventricular hypertrophy and right ventricular hypertrophy, the ability of a single echocardiographic session to detect hypovolemia is severely limited [27].

**Dynamic Parameters**

In the past decade, dynamic parameters (e.g., SV variation, pulse pressure variation, etc.) have gained acceptance as more sensitive indices for assessing fluid responsiveness during mechanical ventilation [28]. Fluid responsiveness is defined as an increase of SV in response to fluid administration. These parameters take advantage of the heart–lung interaction during positive pressure ventilation, as long as the patient is in a regular rhythm. In short, positive pressure inspiration temporarily decreases right-sided venous return and RV SV. The same positive pressure inspiration initially leads to a temporary increase of the LV SV, because the increased intrathoracic pressure compresses the pulmonary veins, pushing blood forward to the LV. The end result is an increased LV SV via Starling forces and greater pulse pressure during the initial portion of inspiration. This is followed by a decrease in the SV effects of both the ventricles during exhalation. This normal phenomenon is exaggerated during hypovolemia. Modern hemodynamic monitors (including those with pulse contour analysis as well as pulse oximetry and discussed in Chapter 28) can quantify these changes using the stroke volume variation and pulse pressure variation to discriminate patients who are fluid responsive from those who are not. These respiratory effects on SV that occur as the result of heart–lung interaction can be assessed with echocardiography.

**Aortic Flow Index**

The aortic flow index (AFI) takes advantage of the heart–lung interaction that is the foundation of fluid responsiveness. This index uses pulse wave Doppler ultrasound to measure changes of the velocity of blood exiting the heart through the LVOT during positive pressure ventilation. In essence, this index is the ultrasound equivalent of the pulse pressure variation. As mentioned earlier, SV increases with initiation of positive pressure inspiration and decreases during exhalation. With ultrasound, higher left ventricular SV translates to higher velocities and VTIs of blood
in the LVOT and ascending aorta. Measuring these flows is relatively easy with either TTE or TEE, and most modern ultrasound machines can be programmed to calculate this index automatically. The AFI is calculated as the difference between the highest and lowest peak velocities measured at the ascending aorta (or even more conveniently in the LVOT) divided by the mean of these two velocities, expressed as percentage (Fig. 29.1). An index of 12% allows discrimination between fluid responders and nonresponders with very high sensitivity and specificity [29].

\[
AFI = \frac{(V_{\text{max}} - V_{\text{min}})}{\frac{(V_{\text{max}} + V_{\text{min}})}{2}} \times 100\%
\]

**FIGURE 29.1** Aortic flow index is measured in the apical 5-chamber view (TTE) or deep trans-gastric view (TEE). The sweep speed is reduced to capture more stroke volume spectral display. While blood flow can be measured in the ascending aorta, it can be also very conveniently measured in the LVOT. Peak flow is measured at the highest and lowest stroke volumes, which represent flow during positive pressure inhalation and exhalation, respectively. Most modern ultrasound machines can be programmed to calculate equations, and, in this example, the aortic flow index is calculated to be almost 24%. LVOT, left ventricular outflow tract; TEE, transeosophageal echocardiography; TTE, transthoracic echocardiography.

**Inferior Vena Cava Distensibility Index**

The IVC, as an extrathoracic structure, dilates during positive pressure inspiration because of increased intrathoracic pressure that resists
venous return to the right heart. During exhalation, it decreases in size. Quantifying the degree of dimensional change of the IVC, defined as distensibility, can help predict fluid responsiveness in patients who are mechanically ventilated with positive pressure ventilation [30,31]. Two different distensibility indices have been described in the literature.

The first distensibility index (dIVC, where the “d” signifies “delta”) is defined as the difference between the maximum IVC diameter at end-inspiration (D_{max}) and the minimum IVC diameter at end expiration (D_{min}) divided by D_{min} and expressed as percentage (Fig. 29.2) [30]. An index larger than 18% defines fluid responsiveness for this index.

\[
dIVC = \frac{D_{max} - D_{min}}{D_{min}} \times 100\%
\]

The second index defines the distensibility as the difference between the maximum diameter at the end of inspiration (D_{max}) and the minimum IVC diameter at end expiration (D_{min}) divided by the mean of the two and expressed as percentage (Fig. 29.2) [31].

\[
dIVC = \frac{D_{max} - D_{min}}{(D_{max} + D_{min})/2} \times 100\%
\]

Using this method, an index larger than 12% defines fluid responsiveness.
Superior Vena Cava Collapsibility Index

Because the superior vena cava (SVC) is an intrathoracic structure hidden by the right lung, it cannot be viewed using TTE. TEE provides the ability to view this vessel relatively clearly. Although the concept is the same as for the IVC distensibility index, being an intrathoracic structure, the effect is reversed, and SVC diameter decreases (or “collapses”) with positive pressure inspiration. The SVC collapsibility index (dSVC) is defined as the difference between the maximum SVC diameter at end expiration (D_{max}) and the minimum diameter at the end of inspiration (D_{min}) divided by the maximum diameter and expressed as a percentage (Fig. 29.3) [32].

$$d_{IVC} = (D_{max} - D_{min})/D_{max} \times 100\%$$

**FIGURE 29.3** A: SVC collapsibility index of a patient who is fluid responsive. B: SVC collapsibility index of a patient who is fluid unresponsive. The SVC diameter is measured with TEE in the upper esophageal window. A cutoff of 36% discriminates between fluid responders and nonresponders; dSVC higher than 36% indicates fluid responders, and dSVC smaller than 36% indicates nonresponders. SVC, superior vena cava; TEE, transesophageal echocardiography.

For this index, a result larger than 36% indicates fluid responsiveness. SVC collapsibility index appears to be more accurate than the IVC distensibility index for predicting fluid responsiveness [33]. This is likely because, physiologically, the SVC and IVC are exposed to significantly different pressures. For example, only 20% of the airway pressure is transmitted to the abdomen [34], and the relationship between venous transmural pressure and venous size is curvilinear [35].
Velocity Time Integral

As mentioned earlier, for monitoring CO response to inotropes or volume expansion, a simple approach to monitoring fluid resuscitation for critically ill patients is simply to serially measure the VTI. VTI is measured in the A5CH view and considered the Doppler surrogate of SV. Therefore, the VTI increases when SV increases as a result of fluid administration. For an average size patient, a normal VTI is larger than 18 cm that corresponds to SV of roughly 60 mL; however, it is the change in response to a fluid bolus that is desired to demonstrate fluid responsiveness.

Passive Leg Raise Test

The passive leg raise (PLR) test has been advocated in recent years as an excellent technique to assess fluid responsiveness for patients subjected to passive controlled ventilation [36] as well as those breathing spontaneously [37]. It is a simple reversible maneuver that mimics rapid fluid loading, thereby increasing the cardiac preload and SV of preload-dependent patients. The technique requires semicontinuous monitoring of CO that can detect short-term and transient changes of CO during the test. In theory, echocardiography may qualify as an approach for monitoring by investigating the change in LVOT by measuring VTI in the semi-recumbent, baseline position and the VTI in the supine position with the patient’s legs elevated. However, technical challenges may limit its use for the PLR test. For example, in a study of the PLR test among healthy volunteers, only 65% of the patients had adequate Doppler images of the VTI for analysis [38]. The ability to obtain adequate Doppler images may be lower among critically patients as a result of obesity, comorbidities, mechanical ventilation, and other factors. Another limitation includes translation of displacement from the motion of the heart when a semi-recumbent patient is moved to the supine position, preventing the sonographer from obtaining a timely recording of the VTI. Finally, with the PLR test, the CO should be measured for 3 to 5 minutes following transition to supine position with elevated legs [39,40], and the highest CO measurement used for the analysis. Therefore, echocardiography is likely to be less attractive for this purpose, because the sonographer is required to first record VTI loops for at least 3 minutes, choose the highest VTI out of these loops and then compare it to the baseline VTI and make the necessary calculations.
Limitations of Echocardiography use for the Assessment of Fluid Responsiveness

Left Ventricular Preload

For over four decades, fluid optimization of critically ill patients was achieved by assessing right and left ventricular preload through measuring central venous pressure (CVP) and pulmonary artery occlusion pressure, respectively. It is now well accepted that filling pressures alone cannot be used to adequately assess ventricular preload [41]. A potentially attractive alternative is echocardiographic assessment of LV preload using direct visualization of left ventricular size and, more specifically, end-diastolic area (LVEDA). Unfortunately, because LV size is a highly variable parameter, LVEDA has a low sensitivity in detecting blood volume changes in critically ill patients [42,43]. In addition, LV size fails to predict fluid responsiveness among patients with shock [44]. Therefore, assessing fluid responsiveness by LVEDA is not recommended. However, in the extreme situation of pure hypovolemic shock, LEVDA may be useful and this is discussed later.

Static Inferior Vena Cava Diameter

The IVC is a very compliant vessel, and it is easily imaged from the subcostal view. Its size and collapsibility are affected by several factors, such as total blood volume, CVP, intrathoracic pressure (which in turn, can be affected by the patient’s respiratory pattern), and intra-abdominal pressure. Despite the attractiveness of using the IVC to diagnose hypovolemia and predict fluid responsiveness using its size and respiratory variability for spontaneously breathing patients, this correlation appears to be poor and unpredictable [45–47]. Therefore, clinicians are discouraged from using the IVC in isolation from other parameters for diagnosing hypovolemia.

Case 1

A 35-year-old man was admitted to the ICU from the operating room after 12 hours of surgery for polytrauma. He underwent extensive vascular surgery of the pelvis, as well as an exploratory laparotomy and splenectomy. He lost a significant amount of blood and was aggressively resuscitated by the anesthesia team with blood products and fluids.

Upon arrival to the ICU, the patient was on low-dose phenylephrine infusion for hemodynamic support. Blood pressure (BP) was 110/55 mm Hg, and lactate was 7.2 mmol per L. Owing to the surgical dressing and
body habitus, only the apical 4-chamber (A4CH) view was available for imaging. It demonstrated no evidence of chronic heart disease or severe hypovolemia. The RV was not well seen, but it appeared to be very small in size and with normal function. Severe hypovolemia was diagnosed based on the presence of LV end-systolic cavity obliteration (commonly known as “kissing walls”), and very small LVEDA using the eyeballing technique. In fact, the LV walls barely separated from each other in diastole (Video 29.2). Based on these findings, a liter of lactated ringer’s solution was rapidly administered, and a follow-up examination showed that both ventricles enlarged in size and volume (Video 29.2). However, both appeared to still be significantly underfilled, as indicated by the small end-diastolic size. Another liter of lactate ringer’s solution was rapidly administered, and the follow-up TTE examination demonstrates further increase in biventricular size that now appeared to be normal (Video 29.2).

Case 2

A 65-year-old woman was admitted to the ICU in septic shock, likely from a urologic source. During intubation in the emergency department, she vomited and aspirated and subsequently became hypotensive. Severe hypotension persisted in the ICU despite infusion of four pressors and inotropic agents. A TEE was performed to help with the management of shock and demonstrated hyperdynamic LV, normal RV function, and high AFI of 24% (Fig. 29.4). After administration of 500 mL of colloid solution, a repeat TEE examination showed that the AFI was reduced to 15% (Fig. 29.5). Further resuscitation with 250 mL bolus of colloid solution reduced the AFI to 11% (Fig. 29.6). Based on these findings, aggressive fluid resuscitation was held at that time. BP stabilized, and the dose of the vasopressor and inotropes was weaned successfully.
FIGURE 29.4  TEE deep transgastric view measuring flow of blood in the LVOT over several cardiac cycles. The spectral display waves with higher blood velocity occur during positive pressure inspiratory cycles and those with lower blood velocity occur during exhalation. The ultrasound machine has been programmed to automatically calculate the aortic flow index once the maximum and minimum peak velocities are measured. LVOT, left ventricular outflow tract; TEE, transesophageal echocardiography.
FIGURE 29.5 TEE deep transgastric view measuring flow of blood in the LVOT of several cardiac cycles after administration of 500 mL of colloid solution. Compared with the baseline examination, the maximum peak flow during positive pressure inspiration slightly decreased from 1.04 to 1.00 m per second and the maximum peak flow during exhalation increased from 0.81 to 0.86 m per second. This narrowing of the difference between the peak flows leads to a reduction of the aortic flow index from 24% to 15%. LVOT, left ventricular outflow tract; TEE, transesophageal echocardiography.

FIGURE 29.6 Same TEE view after resuscitation with a second bolus of 250 mL of colloid solution. This fluid bolus further reduced the aortic flow index to 11%, which changes the patient’s physiology from fluid responsive to unresponsive by the defined limit for normal of 12%. TEE, transesophageal echocardiography.

Pitfalls and Recommendations for use of Echocardiography for Fluid Management

- Assessment of “fluid status” with echocardiography can only be done in the absence of chronic heart disease.
- Except for the extreme condition of severe hypovolemia, static measurements of LV preload by end-diastolic and end-systolic areas cannot predict fluid responsiveness.
- IVC size is affected by many factors and does not correlate with fluid responsiveness. Therefore, it should not be used in isolation to guide fluid management.

- In the absence of chronic heart disease, the pattern of severe hypovolemia includes very small right and left ventricular areas in both end diastole and end systole in the presence of a very small and collapsing IVC.

- The dynamic indices can be useful for predicting fluid responsiveness, but limited only for patients ventilated with positive pressure ventilation, sinus rhythm, and tidal volume of 8 to 10 mL per kg. Cautious should be exercised in patients with RV failure who are passively ventilated because the presence of RV dysfunction may limit left chamber filling and results in a lack of the usual left-sided responsiveness predictors.

- A simple and practical method to assess fluid responsiveness is by improved SV and thus VTI in the A5CH or A3CH views following administration of fluids.
PULMONARY EMBOLISM

Introduction

Venous thromboembolism (VTE) is a spectrum of disease ranging from DVT to pulmonary embolism (PE). In terms of prevalence, VTE is the third most frequent diagnosis among cardiovascular disorders [48]. Although the incidence of VTE is unclear, it is estimated to be approximately 100 to 400 cases per 100,000 people per year [49,50]. VTE is a frequent cause of hospitalization, morbidity, and mortality; it is estimated that 60,000 to 100,000 Americans die annually from VTE, and sudden death is the first symptom in about 25% of people who have PE. In addition, one-half of patients who have had DVT develop long-term complications [51]. This section analyzes the echocardiographic and ultrasonographic findings that are used to evaluate patients suspected of having a VTE. Specific emphasis is placed on the diagnosis of PE and the limitations of ultrasound for this purpose, particularly the issues with sensitivity and specificity for this diagnosis by ultrasound.

Pathophysiology

Although acute PE can interfere with both gas exchange and circulation, the primary cause of death in PE is acute, right-sided heart failure caused by increased pulmonary vascular resistance (PVR) [52]. Right ventricular failure occurs when the RV experiences a sudden and profound increase in afterload from increased PVR. Under normal conditions, the PVR is low because of high compliance of the pulmonary vessels. This relationship changes when more than 30% of the pulmonary arterial vasculature is occluded by thromboemboli, at which point the PA pressure starts to increase [52].

In addition to anatomic obstruction of blood flow, the abrupt increase of PVR is explained by vasoconstriction caused by vasoactive mediators released mainly by activated platelets. Thromboxane A2 and serotonin are likely the two most important pulmonary vasoconstrictors in this context [53], and this hemodynamic effect can be reversed by vasodilators [54,55].

The effects of sudden and significant increases of PVR on the right heart can be devastating. Because the right ventricular free wall is a thin structure, the RV cannot withstand sudden pressure overload. It dilates when exposed to high-pressure conditions, thereby leading to increased wall tension and myocardial stretch. Both processes affect the contractile properties of the right ventricular myocardium, and while increased
catecholamine levels may temporarily help compensate by increasing heart rate and contractility, the RV eventually fails. Its contraction time becomes prolonged into early diastole of the left ventricle (LV). This leads to interventricular septum shift toward the LV, further decreasing CO by reducing left ventricular preload [56] and contributing to hemodynamic instability [57].

RV infarction is uncommon in the setting of acute PE; yet, the presence of elevated levels of myocardial biomarkers (e.g., troponin) suggest RV ischemia as a result of imbalance between oxygen supply and demand [58,59]. This ischemia further exacerbates RV systolic function and contributes to hemodynamic instability.

To summarize the pathophysiology of PE, a large mechanical obstruction of the pulmonary vasculature prevents blood movement from the RV to the left heart. This leads to decreased CO and hypotension. In addition, the sudden and significant increase of RV afterload leads to RV dilatation and increased RV wall tension that frequently causes tricuspid insufficiency. RV pressure overload also leads to septal bowing to the LV, further decreasing CO. It also leads to neurohormonal activation as a compensatory mechanism (e.g., catecholamine release), tachycardia, and increased inotropy. These processes cause an increase of RV oxygen demand and ischemia, that eventually leads to decreased RV contractility, decreased RV CO, hemodynamic collapse, and death.

Role of Echocardiography for the Diagnosis of Pulmonary Embolism

Diagnostic Strategy

The diagnostic strategy for suspected PE might differ based on the hemodynamic status of the patient. In general, computed tomography angiography (CTA) is the gold standard imaging modality for the diagnosis of PE. It allows for adequate visualization of the pulmonary arteries down to the segmental level and potentially beyond [60,61]. Some patients, however, may not have access to CTA owing to either lack of a CT scanner in the treating facility or contraindications such as renal insufficiency, allergy to intravenous contrast, or profound hemodynamic instability, preventing transport of the patient out of the ICU to a remote CT scanner.

It is only in this setting of significant shock with high suspicion of acute PE that echocardiography can be recommended for the diagnosis or
suggestion of acute PE [62]. It is important to realize, however, that despite widespread use of echocardiography during the initial management of acute PE, there is very little published data on its efficacy in this setting. This may explain the recommendation by several societies not to use echocardiography to establish the diagnosis of acute PE [63].

However, strategies that exclude bedside echocardiography from the diagnostic algorithm fail to provide guidance or useful information for patients with life-threatening shock. An alternative strategy recognizes that CTA should be done for all patients with suspicion of PE, unless CTA is not immediately available (such as the case of a patient with hemodynamic collapse who cannot to be transferred to the radiology suite). In this scenario, echocardiography can be used to look for direct and indirect signs of PE [62]. Also of note, TEE will likely provide better image quality than TTE and may allow for direct visualization of thrombi in the PA and its main branches, but is more invasive and, therefore, requires more training.

Adding lower body compression ultrasonography to the workup for PE may be valuable in this setting because up to 50% of patients with PE have also DVT [64–66]. When indicated, it is important to also investigate for upper extremity DVT in this setting. Although less frequent, upper extremity DVT accounts for 10% of all DVT cases [67], and its prevalence appears to be increasing, likely because of the increased use of indwelling central venous catheters as well as peripherally inserted central catheters [68,69]. Thus, echocardiography (TTE or TEE) along with a comprehensive ultrasound examination for DVT is a reasonable diagnostic alternative for patients with no access to CTA who have high probability of PE and shock.

**Echocardiographic Findings**

**Direct Clot Visualization.** Direct clot visualization confirms the diagnosis of acute PE for patients with shock and high suspicion of PE. TTE visualization of thrombi (usually in the right atrium or ventricle) occurs for about 5% of patients with acute PE [70]. TEE can visualize thrombi in the central pulmonary arteries (main, right, and occasionally proximal left PA) more readily than TTE.

**Indirect Signs**

**RV strain and pressure/volume overload.** Indirect signs of PE include RV dilatation, RV free wall hypokinesis (together referred to RV strain), and septal dyskinesia—an abnormal motion of the septum toward the LV. In pure RV pressure overload, the interventricular septum is pushed toward the LV in systole, leading to D-shaped LV during systole in cross-sectional views (Fig. 29.7). In pure RV volume overload, the
interventricular septum is pushed toward the LV in diastole, leading to D-shaped LV in diastole (Fig. 29.8). When the LV is D-shaped during systole and diastole, there is pressure and volume overload.

**FIGURE 29.7** Parasternal short-axis view showing the left and right ventricles (LV and RV, respectively). The interventricular septum is pushed toward the LV during systole (red bar on the ECG tracing), leading to a D-shaped LV. This is indicative of pressure overload.

ECG, electrocardiogram.

**FIGURE 29.8** TEE transgastric short-axis view showing the left and right ventricles (LV and RV
respectively). The interventricular septum is pushed toward the LV at the end of diastole (red bar on the ECG tracing), leading to a D-shaped LV. This is indicative of volume overload. TEE, transesophageal echocardiography.

**McConnell sign.** McConnell sign is a distinctive pattern of pathologic RV free wall regional motion that includes severe RV free wall hypokinesis (and sometimes akinesis) with sparing of the apical portion. That is, the RV apex is spared from hypokinesis/akinesis and contracts normally and may even be hyperdynamic [71]. Originally, McConnell sign was regarded as a highly specific echocardiographic finding for acute PE [71]. However, it is now well accepted that it has poor positive predictive value for diagnosis of acute PE [72,73]. McConnell sign is also seen with other instances of acute cor pulmonale (e.g., RV infarction and acute respiratory distress syndrome [ARDS]) and, thus, should not be used in isolation for the diagnosis of acute PE.

**Doppler signs of PE.** Pulse wave Doppler interrogation of the RVOT and continuous wave Doppler interrogation of the tricuspid regurgitant (TR) jet are used to support the diagnosis of acute PE. Pulse wave Doppler of the RVOT creates a typical spectral display (Fig. 29.9). The acute development of high PA pressure can affect this pattern. Coexistence of short acceleration time (the time from the beginning to peak RVOT flow) and midsystolic deceleration also known as midsystolic “notch”; Figure 29.10 is consistent with severe acute pulmonary hypertension [74]. With acute PE, RVOT acceleration time is much shorter (less than 60 ms) than other causes of pulmonary hypertension [74]. In addition, contrary to initial belief, a heart with baseline normal RV size, wall thickness, and function is unable to generate high PA pressures in the setting of an acute large PE. Echocardiography can be used to estimate PA pressure using the continuous wave Doppler modality and the Bernoulli equation. The simplified Bernoulli equation relates flow across a valve to the pressure difference between two chambers:

\[ \text{RVSP} = 4(\text{TR}_{\text{velocity}})^2 + P_{\text{RA}} \]
FIGURE 29.9 Parasternal short-axis view of the base of the heart with pulse wave interrogation of the right ventricular outflow tract (RVOT). A characteristic spectral display of laminar flow is displayed as a strong signal at the periphery with the center clear of blood and thus seen as black.

FIGURE 29.10 Parasternal short-axis view at the base of the heart with the pulse wave Doppler interrogation of the right ventricular outflow tract
The normal spectral display of the RVOT is replaced with much reduced flow and with a midsystolic notch (arrow). This indicates acute RV pressure overload. RV, right ventricle.

where RVSP is the RV systolic pressure, $TR_{velocity}$ is the maximal velocity of the TR jet (in meters per second), and $P_{RA}$ is an estimate (or measured, when the CVP is available) of the RA pressure [75]. In the absence of pulmonary stenosis, the RVSP equals PA systolic pressure, and as a result, this approach provides a simple and usually accurate estimation of the presence and severity of PA hypertension [75]. In comparison to patients with other causes of elevated PA pressure (chronic proximal PE, patients with COPD, and patients with primary pulmonary hypertension), patients with acute PE have only mild elevation in systolic PA pressure where the average TR peak gradient is only 48 mm Hg [76], indicating mild PA hypertension.

These two Doppler signs—RVOT acceleration time and TR peak jet gradient—have been described as the “60/60 sign”—an RVOT acceleration time of less than 60 milliseconds in the presence of TR pressure gradient of less than 60 mm Hg. Although the “60/60 sign” is not very sensitive, it is very specific (94%) for the diagnosis of acute PE [77].

**Case 3**

A 63-year-old diabetic man with severe peripheral arterial disease was admitted to the hospital with gangrenous right third and fourth digits for which he underwent toe amputation. The immediate perioperative course was uneventful, but, on the day of discharge, he collapsed in his room. He was found to be in pulseless electrical activity (PEA) arrest. Cardiopulmonary resuscitation and advanced cardiovascular life support were initiated, and, as part of the resuscitative efforts, echocardiography was used after return of spontaneous circulation. The parasternal short-axis view (PSAX) view demonstrated a large mass moving between the right atrium and ventricle (Video 29.3). In the setting of an acute event leading to hemodynamic collapse and PEA arrest, the large mass was considered “clot in transit,” and heparin as well as tissue plasminogen activator (tPA) therapy was administered within 15 minutes of the arrest. Follow-up echocardiography 25 minutes after the initiation of therapy demonstrated absence of right-sided mass that was assumed to be a result of the tPA therapy (Video 29.3). Diagnostic angiography confirmed the diagnosis of significant PE with total occlusion of left main PA (Video 29.3).
Case 4

A 45-year-old woman underwent an uneventful laparoscopic esophagectomy for esophageal cancer. The postoperative course was uneventful, and, on the sixth postoperative day, she developed acute respiratory distress necessitating ICU admission. She required immediate intubation and developed profound shock; while on maximum doses of three vasopressors, her systolic BP remained less than 60 mm Hg. A TTE was performed, and the A4CH view demonstrated a massively enlarged RV, RV free wall akinesis with apical sparing (McConnell sign), and a very small and underfilled LV (Video 29.4). The PSAX view demonstrated a D-shaped LV through most of systole and throughout diastole, indicating RV pressure and volume overload (Video 29.4). These image findings are signs of cor pulmonale. Doppler interrogation demonstrated an RVOT pattern with a midsystolic notch and very short acceleration time of less than 60 milliseconds. The TR pressure gradient assessed in the A4CH view was 34 mm Hg, consistent with a positive “60/60 sign.”

In the setting of acute respiratory failure and overwhelming shock without prior history of heart disease, these echocardiographic signs were highly suggestive of acute and massive PE as the etiology of this patient’s shock. Because the patient was hemodynamically unstable, she could not be transported to the CT scanner. She was treated with heparin and tPA after discussion with cardiology and her thoracic surgeon. Roughly 30 minutes later, her hemodynamics stabilized, and a repeat echocardiogram showed an impressive decrease in the RV size, with improved free wall systolic function (Video 29.4). A repeated echocardiographic examination two days later demonstrated complete resolution of the cor pulmonale with normal RV size and function (Video 29.4).

Recommendations and Pitfalls of Using Echocardiography for the Diagnosis of Acute Pulmonary Embolism

- CTA is the gold standard diagnostic modality for acute PE. Generally, echocardiography should be used cautiously in the diagnosis of acute PE.
- Echocardiography may have a role only for patients with acute shock
and high suspicion for a PE (i.e., high pretest probability) who do not have access to CTA.

- Echocardiographic signs of acute PE include evidence of RV strain (RV dilatation, severe RV free wall hypokinesis, or akinesis) and septal flattening indicative of RV pressure and volume overload. These echocardiographic findings are consistent with acute cor pulmonale.

- McConnell sign—severe hypokinesis of the RV free wall with apical sparing is a nonspecific sign for elevated pulmonary pressure (acute cor pulmonale). It is also seen in the settings of RV infarction and ARDS.

- The “60/60 sign”—RVOT acceleration time shorter than 60 milliseconds in the presence of a TR pressure gradient of less than 60 mm Hg—is a nonsensitive but specific sign for the diagnosis of acute PE.

- The decision on how to manage patients with suspected and echocardiographic evidence of PE (e.g., thrombolytic therapy) should be made only after multidisciplinary discussion with experts in managing patients with PE.
PERICARDIAL TAMPOONADE

Introduction

Cardiac tamponade is a clinical syndrome that results from increased intrapericardial pressure and leads to impaired cardiocirculatory function and, ultimately, hemodynamic collapse. It is defined as significant compression of the heart chambers by accumulating pericardial contents, including fluid, blood, tumor, thrombus, pus, and gas—singly or in combination [78]. Rapid recognition of this life-threatening condition is essential for initiating life-saving treatment. Although tamponade is a clinical diagnosis, this section reviews the echocardiographic findings associated with tamponade as well as provides key limitations of using ultrasound for making this diagnosis.

Pathophysiology

The causes of pericardial disease and tamponade are diverse [79]. They include malignancy, infection (e.g., HIV), trauma, complications from myocardial infarction, surgery/procedures, uremia, collagen-vascular disease (e.g., systemic lupus erythematosus), drugs, idiopathic, and others.

The function of the normal volume of pericardial fluid (15 to 35 mL) is most likely lubrication of the pericardial sac in support of cardiac function. Although the pericardium has some degree of elasticity, at any instant, it is relatively inextensible. Because fluid starts to accumulate within the pericardial sac, it initially distends the parietal pericardium by filling the numerous sinuses and recesses of the pericardium. Once the elastic limit is reached, the heart and the pericardial content compete for the fixed intrapericardial volume [78]. Continued fluid accumulation eventually exceeds the pericardium’s ability to stretch. At that point, the pressure within the pericardial sac increases and can quickly exceed the pressure within the heart chambers, eventually leading to their collapse.

Sequence of Chamber Collapse

A cardiac chamber will first show signs of collapse when its pressure is at its lowest during the cardiac cycle. For the ventricles, this time point is just at the beginning of diastole after the blood has been completely ejected. For the atria, this is also during diastole, which, with reference to the cardiac cycle, occurs during ventricular systole. As pressure builds up in the pericardial sac, it will first lead to right heart collapse because the
right heart normally operates at much lower pressures than the left. Therefore, the sequence of chamber collapse, with reference to the cardiac cycle, is the right atrium during systole, right ventricle during diastole, left atrium during systole, and eventually left ventricle during diastole. It is important to keep in mind that some pericardial fluid accumulations may be confined to specific areas. This is most often seen after cardiac surgical procedures or among patients with pericardial septa that form in the setting of chronic pericardial fluid collections, especially when infectious in nature. For these cases, pressure may be exerted only on a specific chamber or chambers, sparing others. This can lead to deviation from the normal sequence of chamber collapse expected based on intracavitary pressures. As the chambers become progressively smaller, diastolic compliance is reduced, leading to reduced preload, low CO, and hypotension.

**Reduced Venous Return**

Venous return is normally bimodal with peaks during ventricular systole and early diastole. It is determined by the pressure difference between the pulmonary veins (which is affected by intrathoracic pressure) and the left atrium. As tamponade becomes more severe and chamber compression becomes more pronounced throughout the cardiac cycle, LA pressure increases. This, in turn, causes venous return to progressively occur during systole as diastolic flow diminishes. The end result is reduced venous return that leads to further reduction of CO and higher degrees of hypotension.

**Ventricular Interdependence**

Ventricular interdependence ([Video 29.5](#)) is the term used to describe the phenomenon of size, shape, and compliance of one ventricle that affects the size, shape, and pressure–volume relationship of the other ventricle through direct mechanical interactions [80]. During tamponade, ventricular interdependence affects hemodynamics to a much greater degree than during normal conditions.

Under normal physiology, there is respiratory variation of venous return to the heart. With normal negative pressure inspiration, the decline of thoracic pressure is transmitted through the pericardium to the right side of the heart, promoting venous return. The effect on the left heart is opposite; the decrease of the intrathoracic pressure decreases the pressure within the pulmonary veins, leading to a decreased pressure gradient to the left atrium and decreased venous return to the left heart.
During tamponade, the heart is isolated from the thorax, thus altering this normal physiology. The stiff pericardium prevents the right ventricular free wall from expanding during inspiration. As a result, the distension of the RV is limited. The structure that can best accommodate diastolic right ventricular filling is the interventricular septum that along with compromised left ventricular filling causes the septum to bulge to the left. The end result is further reduction of left ventricular size and compliance during diastole, contributing even further to decreased left ventricular filling during inspiration. This ventricular interdependence further contributed to lower CO and resulting hypotension.

To summarize, tamponade physiology consists of three processes that contribute to a significant decrease of CO. First, the mechanical compression of heart chambers decreases ventricular size and preload. Second, increased LA pressure results in decreased venous return to the left heart. Third, in the setting of a stiff pericardium, ventricular interdependence leads to diastolic bulging of the interventricular septum toward the LV, further decreasing its preload. These three processes lead to a reduction of CO, which can progress to hemodynamic collapse.

Role of Echocardiography for the Diagnosis of Tamponade

As mentioned previously, it is important to emphasize that tamponade is a clinical and not an echocardiographic diagnosis. Clinical findings of patients with tamponade include sinus tachycardia, tachypnea, distended neck veins, pulsus paradoxus, pericardial rub, muffled heart sounds, and electrical alternans on electrocardiogram. Echocardiography, however, plays a major role in the identification of a pericardial effusion and for assessing its hemodynamic significance [81].

Two-Dimensional Evaluation

Although “size does not matter”—a small effusion can lead to tamponade (e.g., a young trauma patient with small hemopericardium)—in most cases of pericardial tamponade, a moderate-to-large effusion is present. On the other hand, the presence of a pericardial effusion does not necessarily secure the diagnosis of tamponade, and careful echocardiographic evaluation is required in order to make this diagnosis. Typically, cardiac chamber collapse occurs before clinical hemodynamic failure. When assessing for cardiac tamponade, it is important to identify abnormalities of the cardiac cycle where atrial diastole occurs during ventricular systole.
When intrapericardial pressure exceeds intracardiac pressure, collapse of any chamber can occur [82]. Following is a discussion of the individual chamber collapse.

**Right Atrial Systolic Collapse.** The right atrium is a thin, nonmuscular, and compliant structure, with the lowest pressure among all heart chambers (1 to 8 mm Hg) [83]. As a result, when intrapericardial pressure slightly exceeds intracavitary RA pressure, the RA will collapse [84]. Although brief RA collapse can occur in the absence of cardiac tamponade, when it persists for more than one-third of the cardiac cycle, it is highly sensitive and specific for cardiac tamponade [85].

**Right Ventricular Diastolic Collapse.** The RV is a thin muscular structure (up to 5-mm thickness), which like the RA is also susceptible to elevated intrapericardial pressure. The normal right ventricular diastolic pressure is 1 to 8 mm Hg, and the peak systolic pressure is 15 to 30 mm Hg [83]. RV diastolic collapse occurs in early diastole when the RV volume is still low [82]. RV diastolic collapse is less sensitive than RA systolic collapse for the presence of cardiac tamponade, but is very specific for the diagnosis of tamponade [86]. Caution should be exercised when investigating a patient with long-standing pulmonary hypertension because the hypertrophied RV may prevent RV free wall collapse [84].

**Left Atrial Systolic Collapse.** LA collapse is less common than right-sided collapse because the LA operates on a higher intracavitary pressure; the normal mean LA pressure is between 4 and 12 mm Hg [83]. It is seen in only 25% of patients with hemodynamic compromise [87], but it is very specific for cardiac tamponade [81,88,89].

**Left Ventricular Collapse.** Despite having similar diastolic pressure as the LA (LVEDP between 4 and 12 mm Hg) [83], the LV is less likely to collapse owing to its much higher and thicker muscle mass (wall thickness of 11 mm). It can collapse, however, at the end of the tamponade process when intrapericardial pressure becomes extremely high. LV collapse often precedes complete hemodynamic collapse and death.

**Inferior Vena Cava Plethora.** IVC plethora refers to IVC dilatation (>2.1 cm) and less than a 50% reduction in its diameter during inspiration. IVC plethora indicates marked elevation in CVP, as expected in tamponade. IVC plethora is expected in more than 90% of patients with tamponade [90], and, therefore, its absence should raise the suspicion for absence of tamponade physiology.

**Doppler Evaluation**

The ventricular interdependence discussed above can be evaluated using
pulse wave Doppler. It is important to emphasize that this evaluation can be done only for spontaneously breathing patients because positive pressure ventilation can affect ventricular interdependence.

As discussed previously, ventricular interdependence is increased during tamponade, leading to reciprocal changes in left and right ventricular volumes with respiration. Pulse wave Doppler can be used to evaluate the respiratory variation of the tricuspid or mitral valve inflow by measuring blood flow velocities into the RV and LV, respectively. Under normal physiology, the respiratory change in tricuspid flow velocity is no more than 15%, and the change in mitral flow velocity is no more than 10% [91]. During tamponade, flow velocities are significantly increased with inspiration, thus reflecting increased ventricular interdependence (Video 29.5). Usually, changes of mitral flow velocities of more than 30% and tricuspid flow velocities greater than 60% are considered consistent with tamponade physiology [92]. However, in the absence of chamber collapse or abnormal IVC plethora, Doppler evaluation alone should not be used to diagnose tamponade.

**Localized Tamponade**

Presentation of cardiac tamponade among patients after cardiac surgery is often atypical [93] and can pose a serious diagnostic challenge. Effusions that contain clots can be challenging to identify by TTE and are often better evaluated with TEE or CT. A high level of suspicion should be maintained, and consultation with an expert echocardiographer should be solicited for this patient population.

**Case 5**

A 66-year-old man with extensive smoking history was diagnosed with squamous cell lung carcinoma and a medium-sized mass in the left upper lung lobe. He underwent chemoradiation and was treated for the year prior to admission with Coumadin as a result of left lower extremity DVT and bilateral lobar pulmonary emboli. The patient was readmitted 2 weeks after hospitalization for video-assisted thoracoscopic surgery (VATS) and left upper lobectomy. Following an uneventful surgery, he was discharged home but reported malaise following the VATS 2 weeks earlier with significant shortness of breath in the supine position and dyspnea on exertion, all of which has become progressively worse. The patient denied fever, chills, or chest pain. He was admitted to the ICU with significant shortness of breath and became acutely hypotensive.
Bedside TTE demonstrated a large pericardial effusion with RA systolic collapse and right ventricular diastolic collapse (Video 29.5) and mitral valve Doppler inflow pattern consistent with tamponade. The patient was transferred urgently to the cardiac catheterization lab where 1,150 mL of fluid was drained with resolution of his hypotension. The following day, an echocardiogram was repeated to verify resolution of the effusion (Video 29.5).

Case 6

A 35-year-old woman was admitted to the ICU from the emergency department with chest pain and severe shortness of breath when lying supine. The patient had history of aortic insufficiency and aortic stenosis, as well as end-stage renal disease requiring hemodialysis, which was complicated by recurrent episodes of endocarditis. She had undergone several cardiac surgeries for aortic valve replacements, most recently a month prior to this admission.

On physical examination, the patient was sitting in the upright position with significant shortness of breath and difficulty speaking full sentences. Her BP was 105/65 mm Hg, and heart rate was 100 beats per minute with an oxygen saturation of 97% on room air. The patient also suffered from lower back pain and asked for help to turn on her left side. Immediately after turning, her BP decreased to 50/30 mm Hg. She was immediately turned and positioned upright and her BP recovered. A TTE was performed demonstrating a large thrombus compressing the entire right atrium (Video 29.6). Based on this echocardiographic examination, she was urgently taken to the operating room where a large clot was removed.

Role of Echocardiography for the Diagnosis of Pericardial Tamponade

- Tamponade is a clinical and not a radiographic diagnosis. However, echocardiography can be extremely helpful during the diagnostic process.
- “Size does not matter.” Tamponade can occur with even small amount of pericardial effusion (e.g., a young trauma patient with hemopericardium).
- Not all effusions lead to tamponade. Very large effusions—as large as 2 L—can build up over a significant length of time and have insignificant hemodynamic effects (e.g., a cancer patient with slow fluid accumulation).
- 2D echocardiographic evidence of tamponade in chronologic order: RA
systolic collapse, RV diastolic collapse, LA systolic collapse, and LV collapse. In addition, IVC plethora is expected.

- Patients with long-standing pulmonary hypertension and RV hypertrophy can have tamponade without RV collapse.

- Doppler evidence of tamponade includes a respiratory change of the mitral valve inflow velocity of more than 30% and a respiratory change of the tricuspid valve inflow velocity of more than 60%. This reflects increased ventricular interdependence.

- Localized tamponade can occur postcardiac surgery and may lead to diagnostic challenge. Help from expert echocardiographers should be solicited for this patient population.
PUMP FAILURE

Introduction

The term “pump failure” is commonly used to describe clinically relevant systolic dysfunction of either ventricle. Systolic dysfunction can be chronic, acute, or acute on chronic and can be either global or regional or both. Although there can be several causes that can lead to acute or acute on chronic ventricular dysfunction, this section focuses on the common etiologies that lead to shock and the associated echocardiographic findings of the critical care setting.

Septic Cardiomyopathy

Sepsis, a spectrum of disease ranging from systemic inflammatory response syndrome to septic shock, is a leading cause of death in the United States and the leading cause of death among critically ill patients [94–96]. Reversible myocardial dysfunction is a recognized manifestation of this syndrome [97–99], and coronary flow is often preserved or even supranormal [100]. Although cardiac function can be very depressed, death occurs principally because of multiorgan system failure [97,101,102].

Septis-induced cardiac dysfunction likely results from several simultaneous processes, including elevated circulating cytokines, mitochondrial dysfunction, high level of adrenergic stimulation, metabolic changes of cardiomyocytes, myocardial edema, elevated levels of nitric oxide (NO), myofibrillar dysfunction, and others [101]. Myocardial cell death, however, is a rare event during sepsis and likely does not contribute to the reversible functional cardiac depression. Finally, activation of endothelial cells and induction of the coagulation system also contribute to the pathophysiology of sepsis.

The circulatory abnormalities seen during early sepsis and septic shock are related to severe vasodilatation and intravascular volume depletion. This results in significantly reduced preload along with a reduction of CO, ultimately leading to an imbalance of oxygen supply and demand of different organ beds [103]. This process can be improved, however, with adequate fluid resuscitation [104]. The typical pattern of an adequately resuscitated patient with septic shock includes hyperdynamic cardiac function/output with warm extremities as a result of a low systemic vascular resistance (SVR) (i.e., “warm shock”) [105,106]. Some of the initial reports suggested that patients surviving septic shock had significantly higher levels of CO and oxygen delivery content [107,108].
More recent evidence, however, suggests that 40% to 50% of patients with prolonged septic shock develop myocardial dysfunction, which is manifested as a decreased ejection fraction (EF) [109,110]. While EF is dependent on preload, afterload, and contractility, load-independent advanced techniques of assessing myocardial function among patients with sepsis has also demonstrated significant myocardial dysfunction [111]. This myocardial depression may be severe enough to mimic cardiogenic shock (“cold shock”) [112], and it is often reversible with proper management [110,113]. In addition to systolic dysfunction, diastolic dysfunction has been also reported among patients with sepsis and septic shock [114,115]. Recent data suggest higher mortality rates among patients with grade I diastolic dysfunction than in those without dysfunction, which may suggest inadequate volume expansion at the time of ICU admission [116].

**Echocardiographic Findings**

**Warm Shock.** Echocardiographic findings in patients with septic shock depend on the shock state during the evaluation. In “warm shock” with low SVR and high CO, hypovolemia may coexist (the degree of which will depend on the amount of fluid administered by the time the exam is performed). Patients who have undergone adequate fluid resuscitation demonstrate a characteristic pattern of hyperdynamic ventricles (Video 29.7). Unfortunately, this pattern can be confused with the pattern of severe hypovolemia (Video 29.7) because the left ventricular end-systolic area is very small for both. Additionally, ventricular walls may touch at the end systole (end-systolic cavity obliteration, commonly known also as “kissing walls”). The difference between severe hypovolemia and the pattern of septic shock is the diastolic area, which is a surrogate for end-diastolic volume. While end-diastolic area is very small during severe hypovolemia, it is normal or only slightly reduced for patients with septic shock [117].

**Cold Shock.** As noted earlier, up to 50% of patients with septic shock develop myocardial dysfunction. Often, both ventricles are affected simultaneously with a similar pattern of dysfunction [118]. However, for some cases, only left ventricular function is impacted. It is important to identify these patients with depressed myocardial function because the management may change significantly. For example, while aggressive fluid resuscitation is the main recommended therapy for the initial stage of sepsis, once myocardial dysfunction is recognized, therapy may be
changed from fluid therapy to the addition of inotropic support. When using echocardiography for the management of septic patients, it is important to repeat the exam frequently. This allows the clinician to identify patients who transition from the initial presentation of a hyperdynamic cardiac function to the second stage of myocardial depression and systolic heart failure.

Case 7

A 72-year-old female with a history of renal cell carcinoma and nephrectomy and on chemotherapy was admitted to the emergency department (ED) with septic shock. She was diagnosed with perforated sigmoid diverticulitis and was waiting for urgent surgery. She was aggressively resuscitated with 5 L of crystalloid and was on a high-dose norepinephrine infusion. Initial lab work demonstrated pH of 7.15, base excess of −13 and lactate of 5.3 mmol per L. Echocardiography was performed and demonstrated normal right and left ventricular size with hyperdynamic systolic function of both ventricles (Video 29.7). She underwent sigmoid colectomy and Hartmann procedure and was transferred to the ICU after surgery. She had received about 12 L of fluid and blood products and remained on high-dose norepinephrine and vasopressin infusions to support her BP. Lab work on arrival to the ICU demonstrated a pH of 7.19, base excess of −10 and lactate of 4.6 mmol per L. Repeated echocardiogram demonstrated significant change from the baseline exam. Her repeat echocardiogram now demonstrated severe bi-ventricular systolic dysfunction, with an estimated left ventricular ejection fraction of ~10% (Video 29.7). This dramatic change of systolic function was attributed to rapidly developing septic cardiomyopathy. Based on this unexpected finding, fluid administration was stopped and inotropic support with dobutamine was started. The following morning, a third echocardiogram established resolution of the septic cardiomyopathy, and she now was noted to once again have hyperdynamic left-and-right ventricular systolic function (Video 29.7).

Stress Cardiomyopathy

Stress cardiomyopathy, also known as Takotsubo cardiomyopathy, apical-balloon syndrome or “broken heart syndrome,” is a form of acute and usually reversible heart failure that occurs in the absence of obstructive coronary artery lesions. Patients may present with signs and symptoms mimicking myocardial infarction, but there is no angiographic evidence of obstructive coronary artery disease or acute plaque rupture [119,120]. It was first described in Japan in 1990 as Takotsubo cardiomyopathy [119] and, despite gaining worldwide awareness, current understanding of this syndrome is still lacking. It is characterized by
transient systolic and diastolic left ventricular dysfunction with a variety of wall motion abnormalities [121,122], and affects mostly elderly women, with a female to male ratio of 9:1 [123]. While emotional stress was initially implicated as the main trigger for the development of stress cardiomyopathy [124], it appears that physical triggers, such as neurologic or psychiatric disorders, more frequently provoke it in up to 50% of patients [123]. It has been described in patients with subarachnoid hemorrhage [125], epilepsy [126], electroconvulsive therapy [127], traumatic brain injury [128], stroke [129], and anxiety or depression [130].

Excess catecholamine is suggested as having a potential role for the pathogenesis of stress cardiomyopathy [131]. While β-blockers have been proposed as a therapeutic strategy [132], no prospective trials evaluating therapies in stress cardiomyopathy have been performed to-date. Nevertheless, this may be very plausible given that the coronary microcirculation is innervated by neurons originating in the brain stem that mediate vasoconstriction that can potentially lead to microvascular dysfunction and reversible myocardial stunning [133]. In addition, histopathologic findings from cardiac tissue samples obtained from patients with sudden unexpected death during epilepsy or subarachnoid hemorrhage strongly resembled those of patients who died during an episode of Takotsubo cardiomyopathy [134,135].

Patients with stress cardiomyopathy commonly present with symptoms similar to those of an acute coronary syndrome [136], and, therefore, initial diagnosis and treatment of these patients remains challenging. Troponin levels and electrocardiographic changes on admission are not sufficient to differentiate between these two disorders [137]. Therefore, early coronary angiography may be necessary to rule out an acute coronary syndrome and consultation with cardiology is required.

**Echocardiographic Findings**

While the presentation of patients with stress cardiomyopathy varies (e.g., acute substernal chest pain, dyspnea, syncope, and others), in the ICU setting, it is often associated with shock. Stress cardiomyopathy has unique morphology of apical ballooning and relative compensatory hypercontractility of the basal segments. This initial description of left ventricular apical ballooning [119] is the most common form of stress cardiomyopathy (81.7%). However, it is now known that there are three other forms: midventricular type (14.6%), basal type (2.2%), and focal type (1.5%) [123].

Typically, LV function is impaired on hospital admission and resolves within days to weeks after initial presentation (mean 18 days) [138]. However, roughly 22% of patients have serious in-hospital complications.
These rates are equal to or higher than those of patients with an acute coronary syndrome [123]. Patients with stress cardiomyopathy have lower mean left ventricular ejection fraction (40.7% vs. 51.5%) when compared to patients presenting with acute coronary syndrome [123]. In addition to low EF and CO, stress cardiomyopathy appears to predispose these patients to dynamic obstruction of the LVOT, with a high prevalence of 25% in this patient population [139]. With regard to pathophysiology, basal hypercontractility (possibly aggravated by inotropic agents) may accentuate the Venturi effect that draws the anterior mitral valve leaflet toward the interventricular septum during systole. This movement of the anterior mitral leaflet is known as systolic anterior motion (SAM). The end result can be a dynamic obstruction of blood flow through the LVOT and a further reduction in CO. Furthermore, mitral regurgitation may result from SAM and may contribute to the worsening hemodynamic status of the patient. The diagnosis is generally made with 2D echocardiography with the A5CH (Video 29.8) and A3CH views. Continuous wave Doppler is also useful, which can be used to follow the degree of gradient across the LVOT as well as its response to therapy.

There is no single test or imaging modality that can conclusively confirm the diagnosis of stress cardiomyopathy. Therefore, it remains a diagnosis of exclusion for patients with severe myocardial dysfunction in the proper setting. Suggested diagnostic criteria include the findings of transient left ventricular wall motion as described above, absence of obstructive coronary disease on angiogram, new electrocardiographic abnormalities (ST-segment elevation or T-wave inversion), and modest troponin elevation—all in the absence of myocarditis or pheochromocytoma [137]. Because stress cardiomyopathy can mimic an acute coronary syndrome, consultation with cardiology is warranted. Although echocardiography plays a significant role for the diagnosis and management of patients with stress cardiomyopathy, early angiography is still recommended for the initial diagnosis to exclude an acute coronary syndrome. Angiography, however, may not be feasible for some patients (e.g., patients with subarachnoid hemorrhage) because systemic anticoagulation and anti-platelet therapy is contraindicated for these patients. Therefore, management should be decided after multidisciplinary discussion with cardiology and other treating physicians and after carefully reviewing the patient’s history and events leading to hospitalization.
Case 8

A 65-year-old woman was found unresponsive by her husband and she was transported to the hospital where a head CT showed subarachnoid hemorrhage. She underwent successful coiling of a ruptured aneurysm, but developed shock after the procedure. Echocardiography demonstrated severe LV systolic dysfunction and stress cardiomyopathy was presumed owing to the patient’s history and LV apical ballooning (*Video 29.8*). Inotropic support was initiated and the patient underwent daily echocardiograms in the following days until resolution of shock. Two weeks after initial presentation a follow-up echocardiography confirmed resolution of apical ballooning and cardiomyopathy (*Video 29.8*).
CONCLUSION

The ongoing ultrasound revolution is changing the management of critically ill patients. Ultrasound machines have become ubiquitous in ICUs and have long been used for both diagnosis and procedural guidance. In recent years, many clinicians have undergone training in echocardiography and “focused cardiac ultrasound,” leading to a paradigm shift where echocardiography is now becoming an important modality for the management of critically ill patients. Currently, echocardiography is a promising tool to provide the clinician at the bedside with valuable diagnostic information about the etiology of shock (or equally important—rule out common etiologies). However, focused echocardiography can also be used very effectively as a monitor—as demonstrated by the clinical examples of this chapter. It is also very important to understand the limitations of echocardiography and to maintain a high level of skill and knowledge to ensure that patients are not being harmed and to improve outcomes by the optimal use of this modality.

Respiratory function may be simply classified into ventilation and oxygenation, which are quantified by the ability of the respiratory system to eliminate carbon dioxide and form oxy-hemoglobin, respectively. The goal of respiratory monitoring in any setting is to allow the clinician to ascertain the status of the patient’s ventilation and oxygenation. The data must then be used appropriately to correct the patient’s abnormal respiratory physiology. As with all data, it is imperative to remember that interpretation and appropriate intervention are still the onus of the clinician, who must integrate these data with other pieces of information in order to make a final intervention. For the critically ill patient, the principal intervention with regard to respiratory function and monitoring usually involves the initiation, modification, or withdrawal of mechanical ventilatory support. This chapter will focus on respiratory monitoring for the mechanically ventilated patient.

Mechanical ventilation (MV) entails the unloading of the respiratory system via the application of positive pressure to achieve the goal of lung insufflation (i.e., inspiration) followed by the release of pressure to allow deflation (i.e., expiration). These simplified goals of mechanical ventilation are achieved in spite of complex and dynamic interactions of mechanical pressure with the physical properties of the respiratory system, namely, elastance ($E_{rs}$) and resistance ($R_{rs}$). Furthermore, the patient’s overall clinical condition (e.g., neurological or muscular) often times affects the goals of respiration; thus, they need to be monitored and evaluated using an integrative approach. Therefore, this chapter will focus on three specific areas of monitoring for the mechanically ventilated patient: (a) the evaluation of gas exchange, (b) respiratory mechanics, and (c) respiratory neuromuscular function.
GAS EXCHANGE

Basic Physics of Gas Exchange

As mentioned, the primary function of the respiratory system is gas exchange (i.e., elimination of carbon dioxide while instilling oxygen to form oxy-hemoglobin). Inadequate ventilation and oxygenation within the intensive care setting are typically caused by hypoventilation, diffusion impairment, and ventilation–perfusion (V. – Q.) mismatch.

Hypoventilation is defined as inadequate alveolar ventilation and is commonly caused by drug side effects, neurological impairment, or muscle weakness/fatigue, which results in hypercarbia, according to the following equation:

\[ \text{PaCO}_2 = \left( \frac{\text{V. CO}_2}{\text{V. A}} \right) k \]

where \( \text{PaCO}_2 \) is the arterial partial pressure of carbon dioxide, \( \text{V. CO}_2 \) the production of carbon dioxide in the body, \( \text{V. A} \) is alveolar ventilation, and \( k \) is a constant. Fortunately, the institution of mechanical ventilatory support readily corrects hypoventilation while the underlying cause is determined and corrected.

Diffusion impairment is the result of inadequate exchange of oxygen across the capillary-alveolar membrane, resulting in hypoxemia. This may occur due to pathological thickening of the membrane or high cardiac output states such as sepsis. However, the relative clinical significance of diffusion impairment in the intensive care unit (ICU) is debatable. This is because the hypoxemia that results from the acute exacerbation of diffusion impairment is usually corrected by supplemental oxygen therapy. Of note, \( \text{PaCO}_2 \) is rarely affected by diffusion impairments because it is highly soluble and can be eliminated in multiple forms, e.g., as bicarbonate.

The most common cause of hypoxemia in the ICU is ventilation–perfusion (V. – Q.) mismatch. Ventilation–perfusion mismatch is the result of an inequality of the normal ventilation to perfusion ratio within the lung. V. – Q. mismatch is a spectrum of abnormal ratios signifying inadequate gas exchange at the alveolar level. When ventilation is significantly decreased with respect to perfusion (i.e., a V. – Q. ratio << 1), hypoxemia ensues. In general, hypoxemia from V. – Q. mismatch can be overcome with supplemental oxygen. However, in the extreme, as the V. – Q. ratio in an alveolus approaches zero (i.e., no ventilation while the alveolus is still being perfused), it approaches “true shunt.” At the other end of the spectrum, as the ratio in the alveolus approaches infinity (i.e., no perfusion in a ventilated alveolus), it becomes physiologic “dead space.” Dead space will be described in greater detail later in this chapter.
As mentioned, true shunt is one extreme of V\(_t\) – Q\(_t\) mismatch that occurs when ventilation in the alveolus approaches zero with ongoing perfusion. The true shunt fraction is the proportion of the cardiac output that results in venous blood mixing with end-arterial blood without participating in gas exchange. This has little effect on carbon dioxide tension; however, increases in shunt result in worsening hypoxemia. The true shunt fraction is expressed via the shunt equation as follows:

\[
\frac{Q_s}{Q_t} = \frac{(C_c - C_a)}{(C_c - C_v)}
\]

where \(Q_s\) and \(Q_t\) are the shunt and total blood flows, and \(C_c\), \(C_a\), and \(C_v\) represent the oxygen contents of pulmonary end-capillary, arterial, and mixed venous blood, respectively. The absolute oxygen content of arterial and mixed venous blood is calculated according to the oxygen content equation:

\[
Cx = (1.34 \times Hb \times SxO_2) + (PxO_2 \times 0.003)
\]

where \(Cx\), \(SxO_2\), and \(PxO_2\) are the oxygen content, saturation, and partial pressure of oxygen within arterial and mixed venous blood, respectively. The oxygen content of end-capillary blood is estimated by the alveolar gas equation as follows:

\[
C_c = (P_{atm} - P_{H_2O}) \times FiO_2 + PaCO_2/RQ
\]

where \(P_{atm}\) and \(P_{H_2O}\) are the partial pressures of the atmosphere and water (typically 760 mm Hg and 47 mm Hg at sea level), respectively; while \(FiO_2\) is the concentration of inspired oxygen, \(PaCO_2\) is the arterial partial pressure of carbon dioxide and RQ is the respiratory quotient (approximately 0.8 at steady state, but varies depending on the utilization of carbohydrates, protein, and fat). The clinical significance of true shunt is the fact that it is not amenable to supplemental oxygen therapy. Shunted blood re-enters the circulation and dilutes oxygenated blood, resulting in a lower partial pressure of oxygen (PaO\(_2\)) in the arterial system. Increasing the \(FiO_2\) will not improve oxygenation since the shunted fraction of blood does not meet alveolar gas.

Direct Blood Gas Analysis

Monitors of gas exchange for the mechanically ventilated patient are typically directed at measurements of gas content and their gradients.
from the ventilator circuit to the alveolus and from the alveolus to the end-artery. As with most monitors, sources of error abound at many points as gases flow according to their concentration gradients. The most accurate assessment of gas exchange is direct measurement from an arterial blood sample. This provides the partial pressures of carbon dioxide (PaCO$_2$) and oxygen (PaO$_2$) in the blood as well as the pH, base deficit, and co-oximetry of other substances such as carboxyhemoglobin and methemoglobin. Advantages of arterial blood gas (ABG) analysis include the fact that it is a fairly exact representation of the current state of the patient with regard to acid-base status, oxygenation, and ventilation. However, the limitations of blood gas analysis as a tool for monitoring gas exchange are numerous, including the fact that it is invasive, wasteful (blood), expensive, and intermittent (i.e., it is only a snapshot of the patient’s condition at the time the ABG is drawn).

Central and peripheral venous blood gas sampling has been proposed as an acceptable surrogate to arterial blood for monitoring pH, PaCO$_2$, and base deficit [1]. The obvious advantage is that it is less invasive (i.e., patients are not required to have arterial access or punctures), while the disadvantages are the need for correlation and inability to assess oxygenation. With the exception of patients undergoing cardiopulmonary resuscitation [2], good correlation has been observed between arterial and venous pH and PaCO$_2$ among patients with acute respiratory diseases, with one author noting an average difference of 0.03 for pH and 5.8 for PaCO$_2$ [1]. Another study of mechanically ventilated trauma patients also demonstrated good correlation between arterial and central venous pH, PaCO$_2$, and base deficit; however, the authors concluded that the limits of agreement (−0.09 to 0.03 for pH and −2.2 to 10.9 for PaCO$_2$) represented clinically significant ranges that could affect management and therefore should not be used in initial resuscitation efforts of trauma patients [3].

**Pulse Oximetry**

Without question, pulse oximetry has been the most significant advance in respiratory monitoring in the past several decades. Based on the established oxy-hemoglobin dissociation curve (Fig. 30.1), pulse oximetry allows for the continuous, noninvasive estimate of a patient’s oxyhemoglobin and is expressed as a percentage of total hemoglobin. A detailed explanation of pulse oximetry including the physics and limitations is provided in the Chapter “Routine Monitoring of Critically Ill Patients” (Chapter 27).
Expired Carbon Dioxide Measurements

Capnometry is the quantification of the carbon dioxide concentration in a sample of gas. Quantitative waveform capnography is the continuous plotting of carbon dioxide values over time (Fig. 30.2). The inhaled and exhaled carbon dioxide is displayed on the monitor along with its corresponding numerical measurement. When capnography is performed on continuous samples of gas from the airway circuit, a waveform is created whereby the maximum value is expressed in millimeters Hg and termed end-tidal carbon dioxide or PetCO₂.
Capnography can be very useful for assessing changes in a patient’s cardiovascular status. For example, increases in \( P_{et}\text{CO}_2 \) can signify an increase in cardiac output as spontaneous circulation returns during cardiopulmonary resuscitation (CPR) as was shown in several experimental studies [4–6]. According to the 2010 to 2015 American Heart Association (AHA) guideline’s for Advanced Cardiac Life Support (ACLS), continuous quantitative waveform capnography is recommended for confirmation and monitoring of endotracheal tube placement [7]. \( P_{et}\text{CO}_2 \) is also recommended during CPR since it allows providers to monitor CPR quality, optimize chest compressions, and detect return of spontaneous circulation (ROSC). That is, \( P_{et}\text{CO}_2 \) directly monitors ventilation and indirectly measures metabolism and cardiac output. Normal \( P_{et}\text{CO}_2 \) for an adult patient is 35 to 45 mm Hg, and good quality chest compressions in a patient that is endotracheally intubated should result in \( P_{et}\text{CO}_2 \) levels of >10 mm Hg. Einav et al. postulated in their prospective cohort study that computerized \( P_{et}\text{CO}_2 \) carries potential as a tool for early, real-time decision-making during some resuscitations [8]. With return of spontaneous circulation, a significant increase in the \( P_{et}\text{CO}_2 \) to near normal levels can be observed [9]. For a detailed explanation of capnography and its uses, please refer to Chapter 27, “Routine Monitoring of Critically Ill Patients.”

Dead Space Measurements

Dead space is defined as any space in the respiratory system that is ventilated but not perfused, thereby not participating in gas exchange.
Measurement of dead space is a marker of respiratory efficiency with regard to carbon dioxide elimination. Dead space can be subdivided into alveolar and anatomic. Anatomic dead space is the sum of the inspiratory volume that does not reach the alveoli and therefore, does not participate in gas exchange. For mechanically ventilated patients, the anatomic dead space includes the proximal airways, trachea, endotracheal tube, and breathing circuit components from the Y-adapter to the endotracheal tube. In healthy human subjects, anatomic dead space in cubic centimeters is approximately 2 to 3 times the ideal body weight in kilograms, or 150 to 200 mL. Alveolar dead space is the conceptual sum of all alveoli that are ventilated but not participating in gas exchange, otherwise described as “West Zone 1” [10]. Physiologic dead space (V_d) is the sum of anatomic and alveolar dead space volumes and is usually expressed as a ratio of the total tidal volume (V_t) and can be calculated at the bedside using the modified Bohr equation:

\[ \frac{V_d}{V_t} = \frac{\text{PaCO}_2 - \text{P}_{\text{expCO}_2}}{\text{PaCO}_2}, \]

where \( \text{PaCO}_2 \) is the partial pressure of carbon dioxide and \( \text{P}_{\text{expCO}_2} \) is the partial pressure of carbon dioxide in the expired tidal volume of gas. The \( \text{P}_{\text{expCO}_2} \) is difficult to measure, often requiring metabolic monitoring systems. However, volume capnography is a relatively novel and simple approach to estimating \( \text{P}_{\text{expCO}_2} \), involving measurements of carbon dioxide at the Y-adapter, and has been shown to correlate with more complex methods of metabolic monitoring [11]. The \( \text{PaCO}_2 \) can be estimated as end-tidal carbon dioxide, \( \text{P}_{\text{etCO}_2} \); however, this is known to be inaccurate in certain disease states. Therefore, determination of the \( \text{PaCO}_2 \) is most often measured directly via an ABG.

Physiologic dead space, \( \frac{V_d}{V_t} \), is often increased in critical illnesses that cause respiratory failure, such as acute respiratory distress syndrome (ARDS) and chronic obstructive pulmonary disease (COPD). \( \frac{V_d}{V_t} \) can also increase with excessive Positive End Expiratory Pressure (PEEP) due to over-inflation of alveoli, which impedes pulmonary artery blood flow effectively increasing the “West Zone 1” volume. Serial measurements of \( \frac{V_d}{V_t} \) have been shown to correlate with outcomes of ARDS patients [12] and have been used to monitor the degree of respiratory insult and provide prognostic information for critically ill patients [13]. However,
these data have not translated into changes in treatment. Furthermore, Mohr et al. [14] found no appreciable difference in $V_d/V_t$ while studying a series of post-tracheostomy patients successfully weaned from mechanical ventilation versus those who had failed weaning.
RESPIRATORY MECHANICS

Basic Pulmonary Variables

Modern ventilators allow manipulation and measurement of the airway pressures ($P_{aw}$), including peak and plateau, in addition to mean and end-expiratory volumes ($V$) and flows ($V_t$). It is also possible to measure the actual (or total) PEEP ($PEEP_t$) during static hold maneuvers on the ventilator to determine the extent of “air-trapping” or auto-PEEP. Auto-PEEP is also known as intrinsic PEEP ($PEEP_i$) and will be defined later in this chapter. Integration of these measurements allows assessment of the mechanical components of the respiratory system. The mechanical components are influenced by various disease states, and understanding these relationships could promote the delivery of more appropriate ventilator support as well as pharmacologic management.

The airway pressure ($P_{aw}$) is described by the equation of motion and must be equal to all opposing forces. For the relaxed respiratory system ventilating at normal frequencies, the major forces that oppose $P_{aw}$ are the elastive and resistive properties of the respiratory system as they relate to the tidal volume ($V_t$) and flow ($V_t$), respectively:

$$P_{aw} = E_{rs} V_t + R_{rs} (V_t)$$

where $E_{rs}$ and $R_{rs}$ are the elastance and resistance of the respiratory system, respectively. Constant flow inflation in a relaxed, ventilator-dependent patient produces a typical picture as depicted in Figure 30.3 [15]. The rapid airway occlusion method at end-inflation results in zero flow and a drop in $P_{aw}$ from the peak value (PIP) to a lower initial value and then a gradual decrease over the rest of the inspiratory period until a plateau pressure ($P_{plat}$) is observed. The $P_{plat}$ measured at the airway represents the static end-inspiratory recoil of the entire respiratory system [16]. It is important that the $P_{plat}$ measurement is performed when the patient is passive as any inspiratory or expiratory efforts will create an error in the obtained value.
Measurement of the pleural pressures would allow further partitioning of these pressures into the lung (i.e., transpulmonary pressure, $P_L$) and chest wall (i.e., pleural pressure, $P_{pl}$) components using the equation:

$$P_{aw} = P_L + P_{pl}$$

Unfortunately, direct measurements of pleural pressure are not practical in the intensive care setting. Therefore, pleural pressures have often been estimated via an esophageal balloon catheter measuring the pressure in the esophagus ($P_{es}$), which lies in close proximity to the pleura at the mid-lung level. This alters the above equation as follows:

$$P_{aw} = P_L + P_{es}$$

These pressures are presented graphically in Figure 30.4.
FIGURE 30.4  Esophageal pressure tracing (P-eso) can be seen superimposed on the airway pressure tracing (P-air) during pressure control ventilation (PCV). Transpulmonary pressure has been estimated as the difference between these pressures with specific assumptions.

Compliance and Elastance

The static compliance ($C_{st, rs}$) of the respiratory system and its reciprocal, elastance ($E_{st, rs}$), are easily measured at the bedside using the aforementioned end-inspiratory airway occlusion method to produce zero flow and thus negate the resistive forces within the system. The elastance of the respiratory system ($E_{st, rs}$) is simply the pressure gradient between the total PEEP ($PEEP_t$) and the plateau pressure ($P_{plat}$) divided by the tidal volume ($V_t$) to yield the following equation:

$$E_{st, rs} = \frac{P_{plat} - PEEP_t}{V_t}$$

$E_{st, rs}$ may also be separated into its lung ($E_L$) and chest wall ($E_{cw}$) components by applying this equation to the $P_L$ and $P_{es}$ tracings obtained using $P_{es}$ tracings (see Fig. 30.4) and by the equation:

$$E_{st, rs} = E_L + E_{cw}$$

The relative contributions of the lung and chest wall to the total elastance may be dependent on the etiology of respiratory failure. By way of example, pulmonary edema, either cardiogenic or as a result of ARDS, will lead to an elevated lung elastance ($E_{st}$) and reduced compliance. ARDS of a nonpulmonary origin, sepsis as an example, may also lead to edema of the chest wall and abdominal distension. Both of these will lead
to an additional increase in the elastance of the total respiratory system \( (E_{st, rs}) \) as a result of an increase in the elastance of the chest wall \( (E_{cw}) \).

**Resistance**

According to Ohm’s law, resistance is a function of the airway pressure gradient \( (\Delta P_{aw}) \) divided by flow \( (V \cdot t) \). Respiratory system resistance is a complex and dynamic construct that relates the difference of alveolar to airway opening pressures to airflow. Airway resistance can be measured for ventilator-dependent patients by using the technique of rapid airway occlusion during constant flow inflation. The resistance of the respiratory system \( (R_{RS}) \) can be estimated as:

\[
R_{RS} = \frac{P_{peak} - P_{plat}}{V}
\]

\( R_{RS} \) reflects intrinsic resistance of the airways, dynamic tissue interactions based on respirophasic changes on airway geometry including the pendelluft effect, resistive effects of mucus, blood, cellular debris, and other airway contents, and the viscoelastic properties of the gasses moving through them. Recognizing that airway resistance is abnormally high suggests that airway tube position and patency should be verified, airway contents removed by suctioning or cleaning the tube, and that the bronchodilator administration may be indicated.

**Intrinsic PEEP (Auto-PEEP)**

The desired PEEP set by the clinician on the ventilator is the target pressure at end-exhalation. However, the actual pressure remaining in the alveoli and ventilator circuit at end-exhalation may be higher due to flow limitations or early closing capacity within a patient’s lungs. The actual pressure at end-exhalation is called total PEEP \( (PEEP_t) \), and the difference between the set PEEP and \( PEEP_t \) is referred to as the intrinsic PEEP \( (PEEP_i) \). \( PEEP_i \) can be measured on most modern ventilators during a static breath hold maneuver during exhalation (Fig. 30.3), when the ventilator is able to measure the remaining pressure in the circuit and lungs to determine the \( PEEP_t \) and thus the \( PEEP_i \). As with \( P_{plat} \) measurements, care must be taken to ensure \( PEEP_t \) measurements are made while the patient is passive to avoid errors due to muscle activity. Especially among patients with severe obstructive pulmonary disease (e.g., asthma or COPD), \( PEEP_i \) can impact the ability to trigger the mechanical ventilator. Such patients often have high resistance to both inhalation and exhalation and may not complete exhalation prior to the
next inspiratory cycle. Dynamic hyperinflation is the result of increasing PEEP$_i$ in the airway circuit with each breath (“breath-stacking”) due to the PEEP$_i$ and results in increasing dead space and over-distension. Respiratory rate, I:E ratio, and severity of obstructive pulmonary disease all influence the PEEP$_i$ and therefore may worsen dynamic hyperinflation. Care must be taken to set the high airway pressure ventilator alarms properly and to recognize significant increases in PEEP$_i$ to minimize the risk of dynamic hyperinflation, which can lead to decreased cardiac output and barotrauma (e.g., pneumothorax). For intubated patients breathing spontaneously, high PEEP$_i$ can result in ineffective triggering and increased WOB, which will be discussed later in this chapter. It is worth noting that manipulations of respiratory rate and tidal volume that do not reduce the patient’s overall minute ventilation will rarely reduce the PEEP$_i$ level.

Driving Pressure

Driving pressure ($\Delta P$) is the absolute pressure required to attain a given tidal volume and is proportional to the respiratory system compliance. It can be expressed by the equation:

$$\Delta P = \frac{V_t}{C_{st,rs}}$$

where $\Delta P$ is the driving pressure, $V_t$ is the tidal volume, and $C_{st,rs}$ is the static compliance of the respiratory system. In patients without spontaneous respiratory efforts, the driving pressure is simply the difference between plateau pressure and PEEP. In a retrospective study analyzing the variation and trends for a number of respiratory variables, Amato et al. demonstrated that changes in $\Delta P$ were most predictive of mortality [17]. Specifically, the authors found that a single standard deviation increment in $\Delta P$ (approximately 7 cm of water) was associated with a significant increase in mortality (relative risk, 1.41; 95% confidence interval [CI], 1.31 to 1.51; $p < 0.001$) [17]. The authors noted that this risk persisted even for those patients receiving “lung protective” tidal volumes and plateau pressures, whereas individual changes to tidal volume and PEEP were not independently associated with mortality [17]. Amato and co-authors have argued for a ventilator strategy in which PEEP and tidal volume are manipulated with the specific goal of minimizing $\Delta P$. However, prospective trials are needed to determine whether $\Delta P$ can be manipulated to affect survival or it is merely a marker for disease severity.
and progression.

**Pressure Volume Curves**

**Static Measurements of the Pressure–Volume Curve**

The gold standard of pressure–volume (P–V) curve measurement is the super-syringe method. Using a calibrated syringe, in increments of 50 ± 100 mL, gas is used to inflate the lung up to a total volume of 1,000 ± 2,000 mL. After each increment, the static airway pressure is measured during a pause lasting a few seconds during which there is no flow and the pressure is the same in the entire system from the super-syringe to the alveoli. The lung is then deflated in the same manner and the pressure at each decrement of gas is recorded and the inspiratory and expiratory P–V curves are plotted. Continued oxygen uptake from the blood during this slow inflation-deflation cycle, coupled with equalization of the partial pressure of CO\textsubscript{2} in the blood and alveoli, will lead to a decrease in the deflation volume as compared to the inflation volume of gas. This artifact may appear to contribute to the phenomenon of hysteresis. The more important mechanical cause of hysteresis is based on the slow inflation of the lung during the P–V curve maneuver. This slow inflation recruits areas of the lung with slow time constants and collapsed alveoli. This again will lead to a decreased expiratory volume and hysteresis.

**Semistatic Measurements of the Pressure–Volume Curve**

There are two methods for obtaining semistatic measurements of the P–V curve. These methods do not require the specialized skill and equipment needed for the super-syringe technique. The *multiple occlusion technique* uses a sequence of different-sized volume-controlled inflations with end-inspiratory pauses [18,19]. Pressure and volume are plotted for each end-inspiratory pause to form a static P–V curve. If expiratory interruptions are done as well, the deflation limb of the P–V curve may also be plotted. This process may take several minutes to complete, but yields results close to those obtained by static measurements. The second method is the *low-flow inflation technique*. This technique uses a very small constant inspiratory flow to generate a large total volume. The slope (compliance) of the curve is parallel with a static P–V curve only if airway resistance is constant throughout the inspiration. This is likely not the case as the low flow lessens airway resistance. The low flow also causes a minimal but recognizable pressure decrease over the endotracheal tube, which means
that the dynamic inspiratory pressure volume curve will be shifted to the right [20,21]. The long duration of the inspiration produces the same artifacts as the super-syringe technique, which is represented as hysteresis. Another drawback of static and semistatic methods is that they require stopping therapeutic ventilation while the maneuver is performed. Therefore, the question has been raised if these maneuvers are relevant in predicting the mechanical behavior of the lung under dynamic conditions, where resistance and compliance depend on volume, flow, and respiratory frequency.

**Dynamic Measurements of the Pressure–Volume Curve**

Dynamic measurement of the P–V curve allows continuous monitoring of the respiratory mechanics and in particular of the response to ventilator changes. These measurements are done with the patient on therapeutic ventilator settings whereby pressure is plotted against tidal volume to produce a dynamic P–V curve. However, the pressures are most commonly recorded proximal to the endotracheal tube and are thus heavily influenced by the resistance of the endotracheal tube. Neither the peak pressure nor the end-expiratory pressures are accurately recorded at this position, thus leading to an underestimation of compliance [19].

**Clinical use of the Pressure–Volume Curve**

There is a characteristic shape to the static respiratory system P–V curve of patients with injured lungs. This shape includes an S-shaped inflation curve with an upper and lower inflection point (UIP and LIP respectively; Fig. 30.5), an increased recoil pressure at all lung volumes and reduced compliance (Fig. 30.6), which is seen in the slope of the inflation curve between LIP and UIP. The LIP has often been considered the critical opening pressure of collapsed lung units and has been used as a method of setting the optimal PEEP in patients with acute lung injury. The pressure at the UIP, in turn, was considered to indicate alveolar over-distension that should not be exceeded during mechanical ventilation [22]. These ideas have been challenged for multiple reasons. Accurate identification of the LIP and UIP is challenging even for experienced clinicians [23]. Additionally changes in the P–V curve are not specific for alveolar collapse and have been observed in saline-filled lungs, such as would be seen in patients with pulmonary edema [24,25]. When applied clinically to patients mechanically ventilated with ARDS, Amato et al. [26] demonstrated that use of the P–V curve and titration of PEEP to a level that exceeds the LIP may be part of a successful lung protective strategy. It is unclear from this study, however, what the relative importance of the higher levels of PEEP was in the context of the
ventilatory strategy, which included delivery of low tidal volumes and the use of intermittent recruitment maneuvers.

**FIGURE 30.5** Schematic representation of normal pressure–volume curve (PV curve) with upper and lower inflection points (UIP and LIP, respectively) delineating the more compliant portion of the inspiratory limb and corresponding tidal volume that has been proposed as an “open lung” approach to ventilation in ARDS.

**FIGURE 30.6** Schematic representation of altered compliance (C) and the effect on the volume-pressure (V/P) curve as occurs with pulmonary edema.
Subsequent trials have confirmed the survival benefit for patients ventilated using low tidal volumes; however, studies with higher PEEP have been mixed. Although several early high PEEP trials were negative [27, 28], these trials were criticized for not using a physiological basis to guide PEEP as Amato had done. In a randomized controlled trial involving 983 patients with ARDS, Meade et al. compared an established low tidal volume ventilation strategy with an experimental strategy based on the original “open lung” approach (combining low tidal volume, lung recruitment maneuvers, and high PEEP) [29]. The authors found no significant difference in all-cause hospital mortality or barotrauma, but the “open lung” strategy appeared to improve secondary endpoints related to hypoxemia and use of rescue therapies [29]. Another trial by Mercat et al. was aimed to evaluate the optimal level of PEEP by assigning patients to a moderate PEEP strategy versus an increased recruitment strategy during which the level of PEEP was set to reach a plateau pressure of 28 to 30 cm H₂O [30]. While this study utilized a physiological variable for PEEP titration (based on plateau pressures), they did not find a significant reduction of mortality. However, the authors reported an improvement of lung function and reduced duration of mechanical ventilation as well as duration of organ failure [30]. In a secondary analysis of the aforementioned trials, Goligher et al. found that patients with ARDS who responded to increased PEEP by improved oxygenation had a lower risk of death and postulated that the response to PEEP might be used to predict whether patients would benefit from higher versus lower PEEP levels [31]. In summary, the optimum level of PEEP remains elusive and a matter of ongoing debate and subject for further trials.

Stress Index

In recognition of the various difficulties encountered in determining the LIP and UIP of the P–V curve, the “stress index” was developed as a tool to determine optimal PEEP settings for injured lungs. The stress index is a dimensionless number, the coefficient \( b \) of the following power equation:

\[
\Delta P_{aw} = a \times \Delta t^b + c
\]

and describes the shape of the airway pressure–time curve during constant flow tidal inflation. In this equation, \( \Delta P_{aw} \) is the change in airway pressure over time \( t \); the coefficient \( a \) is the slope of the curve; and
coefficient \( c \) is the value of \( P_{aw} \) at time 0. A stress index (SI) <1 (progressive increase in slope over tidal inflation) suggests tidal recruitment throughout tidal inflation, whereas a SI >1 (progressive decrease in the slope) suggests hyperinflation and a SI = 1 suggests adequate alveolar recruitment without over-distending the lungs [32]. Although large clinical trials on the use of Stress Index for PEEP titration are lacking, Grasso et al. showed that alveolar hyperinflation for patients with focal ARDS ventilated with the ARDSnet protocol is attenuated by a physiological approach to PEEP setting based on the stress index [32]. Several other experimental and small clinical studies have shown that when ventilatory parameters are adjusted to a noninjurious SI (0.95 to 1.05) [33], there is a decrease in lung inflammation and lung injury [33–35]. Ferrando et al. found in their experiment with a swine model that setting the tidal volume to a noninjurious stress index in an open lung condition improved alveolar ventilation and prevented over-distension without increasing lung injury [36]. However, large clinical trials with mortality benefit are lacking; therefore, the use of this measurement has not been incorporated into routine clinical practice.

Separating the Lung and Chest Wall Components of Respiratory Mechanics

Esophageal Pressure Monitoring

Ventilator-induced lung injury (VILI) arguably depends on the transpulmonary pressure \( (P_{aw} - P_{pl}) \), whereas current recommendations for management of ARDS specify limits for pressure applied across the whole respiratory system and are based on pressures measured at the airway. This approach could be seriously misleading if \( P_{pl} \) were to vary substantially among patients. In healthy subjects and upright spontaneously breathing patients, \( P_{pl} \) is often estimated by measuring esophageal pressure \( (P_{es}) \); however, this has rarely been done for critically ill patients with respiratory failure and ARDS, possibly because of a widespread, but untested, belief that artifacts make \( P_{es} \) unreliable as an estimate of \( P_{pl} \) [37]. However, in a lung-injured canine model, Pelosi et al. demonstrated good correlation at mid-lung height between an esophageal balloon catheter measuring the pressures in the esophagus

---

p. 261 p. 262
(\(P_{es}\)) and the pleural pressures measured via pressure-transducing wafers inserted directly in the thorax \([38]\). Although the absolute values of the esophageal pressures were not identical with the pleural pressures, Pelosi noted the excursions of esophageal pressure were the same as those observed in the directly measured pleural pressures. The authors therefore concluded that the changes in esophageal pressures were accurate, but the absolute values were not \([38]\). Others have postulated the explicit assumption that absolute values of \(P_{es}\), corrected for a positional artifact, may reliably reflect an effective \(P_{pl}\) in critically ill patients \([39]\).

Variations of \(P_{pl}\) may have contributed to inconsistent outcomes among clinical trials of ventilation strategies in ARDS. Whereas one large-scale randomized trial demonstrated a survival benefit from use of low tidal volume ventilation, results from other studies have been equivocal \([27,40,41]\). It is possible that in some patients with high \(P_{pl}\), low tidal volume ventilation coupled with inadequate levels of PEEP results in cyclic alveolar collapse at end-expiration. In such cases, resulting atelectrauma might negate the benefit of limiting tidal volume. Similarly, higher levels of PEEP have been shown to be lung-protective in numerous animal models of ARDS but have demonstrated inconsistent benefit in clinical investigations \([26,28]\). This too may reflect failure to account for \(P_{pl}\), leading to under- or over-application of PEEP in some patients as well as misinterpretation of high plateau airway pressures as evidence of lung over-distension \([42,43]\). Measuring \(P_{es}\) to estimate transpulmonary pressure may allow ventilator settings to be individualized to accommodate variations in lung and chest wall mechanical characteristics. Such an individual approach may reduce the risk of further lung injury during ARDS \([37,42,44]\). This was the hypothesis of a single-center, randomized control trial (EPVENT Trial) of 61 patients by Talmor et al. in which ARDS and ALI patients with low-tidal lung protective ventilation were randomized to a high or low PEEP group. Uniquely when compared to prior trials, the intervention group received PEEP based on the contribution of the chest wall as measured by esophageal pressure manometry. The control group received PEEP based on the PEEP:FiO\(_2\) tables from earlier trials that were created from expert opinion and without individualization based on physiologic measurements. The primary endpoint was oxygenation (\(PaO_2:FiO_2\)) with secondary endpoints of compliance, ventilator free days, and mortality. The authors demonstrated that ventilation with a strategy that utilized esophageal pressures measurements to determine PEEP settings was superior as evidenced by improved oxygenation, compliance, and a trend towards improved mortality \([45]\). A multicenter, prospective, randomized
follow-up study is currently being conducted to examine the impact of mechanical ventilation directed at maintaining a positive transpulmonary pressure in patients with moderate-severe ARDS [46].

**Gastric Pressure**

Esophageal pressure monitoring is not a trivial task, requiring specialized equipment and experienced operators. Gastric pressure may provide a reasonable surrogate measure for $P_{pl}$. In a prior study, Talmor et al. [39] have demonstrated that there is a correlation between pressure measured in the esophagus and gastric pressures (Fig. 30.7). This relationship may be particularly important in patients suffering from ARDS, resulting from extrapulmonary causes, where abdominal distension and hypertension may contribute significantly to alveolar collapse.

![FIGURE 30.7](image) This graph demonstrates the correlation between pressures measured in the esophagus ($P_{es}$) and gastric pressure ($P_{ga}$).

**Bladder Pressure**
An alternative measurement of intraabdominal pressure may be obtained by measuring the pressure in the urinary bladder [47]. Instilling 50 to 100 mL of sterile water through a Foley catheter, clamping the catheter, and measuring the resulting bladder pressure have been shown to correlate well with intraabdominal pressure measured through a gastric tube [48]. These pressures have also been shown to correlate well with esophageal pressures [49]. Studies are still required to validate the use of any of these measurements in the clinical care of patients with respiratory failure.

**Respiratory Neuromuscular Function**

During mechanical ventilation, the clinician aims to unload the patient’s failing respiratory system and thereby reduce the work of breathing in the setting of respiratory failure [50]. Obviously, this goal is temporary with the later goal of weaning mechanical ventilation once the patient begins to recover from his or her disease process. To accomplish these goals, the clinician needs to have an understanding of the patient’s respiratory function, which impacts each of these goals differently. For example, complete unloading of the respiratory system is common in the operating room with general anesthesia, muscle relaxants, and controlled mechanical ventilation. However, the use of deep sedation and muscle relaxants for prolonged periods in the ICU has deleterious effects on the latter goal of ultimately preparing critically ill patients for extubation with several studies demonstrating increases in ventilator days, hospital length of stay, and associated costs [51–53]. Furthermore, assisted modes of ventilation with partial unloading have been surmised as beneficial for maintaining the conditioning of the diaphragm and reducing sedation requirements in the critical care setting [50,54]. No one has defined the ideal degree of unloading [50], which would presumably vary by individual and disease state. Nevertheless, it is helpful to understand and quantify the patient’s neuromuscular function in order to facilitate unloading of the respiratory system, minimize patient–ventilator dyssynchrony, and ultimately wean patients from ventilatory support. This requires an understanding of respiratory neuromuscular physiology and how it cooperates with the ventilator. This relationship has been termed *patient–ventilator interaction*.

**Respiratory Neuromuscular Anatomy**

The respiratory system is involuntarily controlled by specialized neurons in the pons and medulla oblongata that control both inspiration and expiration. These neurons in the brainstem coordinate many inputs and feedback loops to control respiration and ensure adequate gas exchange. The specific types of feedback can be mechanical, chemical, and
behavioral, all of which directly affect the neurons’ rate and intensity of neural firing [55]. Together these neurons and their feedback loops constitute the respiratory control center. Under normal resting conditions, neurons in the inspiratory center stimulate contraction of the diaphragm and intercostal muscles via the phrenic and spinal nerves, which creates a negative force in the chest cavity relative to the airway (i.e., a pressure gradient), thus allowing air to flow into the lungs (Fig. 30.8). Subsequent exhalation is typically passive and air is exhaled as a consequence of lung and chest wall elastance or recoil. However, when the respiratory center is stimulated in the presence of carbon dioxide, acidosis, or hypoxemia, exhalation can be made more active by contraction of abdominal and chest wall muscles. The cerebral cortex has the ability to take control of the respiratory system by overriding the brainstem to change the frequency, depth, and rhythm of respirations. This is of minimal concern in the mechanically ventilated patient, whose cerebral cortex is often sedated, either by medications or by illness, such that respiratory neuromuscular function is typically under the control of the brainstem as described above.

**FIGURE 30.8** Spontaneous ventilation with continuous positive airway pressure (CPAP) at 7.5 mm Hg. Airway and esophageal pressure tracings are superimposed and marked as A and B, respectively. Note the onset of inspiration and flow, marked by the first vertical line, as esophageal (P-eso) and airway (P-air) pressures separate, creating a pressure gradient. Flow then ceases, as marked by the second vertical line, when the expiratory valve is opened on the ventilator and airway pressure quickly decreases.
The muscular component of the respiratory system has been described as a pump that, when stimulated, creates a pressure, $P_{\text{mus}}$ [55]. During assisted mechanical ventilation, this pressure can be added to a second pump, which is the airway pressure generated by the ventilator, $P_{\text{aw}}$. The sum of these two pressures, $P_T$, provides the total driving pressure for inspiratory flow [55]. Although neglecting inertia, the equation for motion in the respiratory system states that $P_T$ is dissipated while overcoming the elastive and resistive properties of the lungs as follows:

$$P_T = P_{\text{mus}} + P_{\text{aw}} = (E_{rs} \times V_t) + (R_{rs} \times V)$$

where the variables represent elastance ($E_{rs}$), tidal volume ($V_t$), resistance ($R_{rs}$), and flow ($V$) in the respiratory system [55]. Since the ventilator generated pressure, $P_{aw}$, is intended to unload the patient’s respiratory muscles, it should be synchronous with the neural impulses generated by the respiratory center and thus $P_{\text{mus}}$. To be synchronous with the patient driven inspiration, the ventilator would need to initiate support simultaneously with the patient’s neural firing at the onset of inspiration, continue this support throughout the neural firing, and stop support at the end of neural firing. In reality, this goal is extremely difficult to achieve, though a newer mode of mechanical ventilation—Neuraly Adjusted Ventilator Assist (NAVA)—which will be described later in this chapter, delivers a pressure that is directly proportional to the integral of the electrical activity of the diaphragm. Rather than monitoring neural impulses, most modern ventilators sense changes in pressure and flow within the circuit in an effort to match the patient’s respiratory cycle. The variables that we will discuss in regard to the patient–ventilator interaction include ventilator triggering, cycling-off, and delivery of gas between these two events (i.e., the post-trigger phase). However, it is essential to first define some of the measures of respiratory drive and effort that are commonly used to assess patient–ventilator interaction and weaning such as work of breathing, pressure–time product, airway occlusion pressure, maximal inspiratory force, vital capacity, and rapid shallow breathing index.

**Work of Breathing**

A patient’s respiratory effort is typically discussed and quantified via some measure of the patient’s “work of breathing.” *Work* is defined as the force acting on an object to cause displacement of that object. Therefore, mechanical “work of breathing” includes the measurement of a force...
required to create a change in volume of gas and is expressed in Joules per liter. However, measurements that are based on volume frequently fail to account for the work done by the diaphragm and respiratory muscles during isometric contraction against a closed valve [56], as occurs prior to triggering in some assisted modes of ventilation. The pressure–time product (PTP), which measures swings in intrathoracic pressure via an esophageal pressure monitor and correlates with oxygen requirements of breathing, is considered superior for quantifying a patient’s effort and degree of unloading [50]. This is a calculation of the difference in the time integrals between esophageal pressure, \( P_{es} \), during assisted breathing, and the recoil pressure of the chest wall during passive breathing at a similar tidal volume and flow [56].

**Airway Occlusion Pressure**

Airway occlusion pressure at 0.1 seconds (\( P_{0.1} \)) is an indicator of respiratory drive and is determined by measuring the pressure in the airway a tenth of a second after the onset of inspiration, beginning at functional residual capacity (FRC). This has been shown to correlate well with work of breathing during pressure support ventilation [56]. Therefore, several authors have advocated its use as a potential predictor for discontinuation of mechanical ventilation [57–60]. The threshold value for \( P_{0.1} \) of 6 cm H\(_2\)O appeared to delineate success versus failure in one study. Although the utility of this measurement is still debated, it has been incorporated into several commercially available ventilators.

**Maximal Inspiratory Force**

Maximal inspiratory pressure (MIP), also known as negative inspiratory force (NIF), is another marker of respiratory muscle function and strength and is determined by measuring the maximum pressure that can be generated by the inspiratory muscles against an occluded airway beginning at FRC. A normal value is considered to be approximately 80 cm H\(_2\)O, with respiratory compromise typically observed at values less than 40% of normal. The major disadvantage and limitation of this measurement is the fact that it is extremely effort dependent, which can make its measurement as well as interpretation difficult in severely ill, sedated, and neurologically impaired patients.

**Vital Capacity**

Vital capacity (VC) is the sum of tidal volume, inspiratory reserve volume, and expiratory reserve volume. Forced vital capacity (FVC) is measured
by instructing a patient to inspire maximally to total lung capacity (TLC), followed by forced expiration while measuring the expired volume as the integral of the flow rate. FVC has also been used as an indicator of respiratory muscle function. However, similar to MIP, FVC is also effort dependent and therefore can lead to variable results. With limited success, it has been used to monitor trends in respiratory muscle strength in patients with neurologic impairment and muscle disorders such as cervical spine injury, myasthenia gravis, and the Guillain–Barré syndrome [61–63].

**Frequency/Tidal Volume Ratio**

Respiratory distress is often marked by tachypnea and decreased tidal volumes, leading to inadequate ventilation and increases in PaCO$_2$ secondary to disproportionate ventilation of anatomic dead space and inadequate alveolar ventilation. Therefore, the ratio of frequency to tidal volume, also known as the rapid shallow breathing index (RSBI), has been used to gauge respiratory distress and facilitate weaning and readiness for extubation [59,64–66]. As a criterion for extubation, the RSBI has had mixed success. Values of 100 to 105 breaths/min/L are typically used as a cutoff to predict extubation success from failure. The RSBI is limited by the fact that rapid and shallow breathing, although sensitive indicators of respiratory distress are not specific. For example, pain and anxiety are also consistent with an abnormally high RSBI and are common among critically ill patients weaning from mechanical ventilation. In a clinical trial using a RSBI of <105 as a strict criteria for a spontaneous breathing trial (SBT), the authors found that a weaning protocol that required a favorable RSBI leads to more time on the ventilator without affecting extubation success [67]. Therefore, the RSBI should not automatically prevent the clinician from proceeding with an SBT unless there is just reason and it may be better as a monitor of progress rather than as a strict extubation criterion. For a more detailed explanation of RSBI and ventilator discontinuation, please see Chapter 168, “Discontinuation of Mechanical Ventilation.”
PATIENT VENTILATOR INTERACTION

Ventilator Triggering Variable

During assisted modes of ventilation, the patient’s inspiratory effort is sensed by the ventilator, which is then “triggered” to deliver support at a preset volume or pressure (Fig. 30.9). There are two distinct methods of triggering the ventilator—pressure and flow. **Pressure triggering** depends on the patient’s inspiratory effort, creating a change in pressure that exceeds a preset requirement (typically −2 cm H₂O) to open the inspiratory valve on the ventilator and initiate ventilator support. Likewise, **flow triggering** depends on a patient’s inspiratory effort creating flow detected by a flow meter within the inspiratory limb that exceeds a preset threshold (typically 2 L per minute) for triggering the ventilator inspiratory support. The significant difference between these two triggering criteria is the presence of a closed demand valve in the inspiratory limb of pressure-triggered ventilators. In general, flow triggering has been considered superior to pressure-triggered algorithms in that it is believed that the work of breathing is less in a system that does not require an initial inspiratory effort against this closed valve. Many studies have compared flow triggering and pressure triggering with respect to work of breathing with most showing significant advantages in favor of flow-triggered systems [68–70]. This is partially explained by the fact that flow triggering results in improved responsiveness with shorter delay between onset of diaphragm contraction and ventilator triggering [70].
Normal triggering in assist-control ventilation. The circles marked A denote the pressure and flow that correspond to patient neural inspiration that is detected by the ventilator and leads to delivery of a mechanical breath.

The main variable that can be controlled on the ventilator with regard to triggering is termed sensitivity. Typical values for pressure triggering are 1 to 2 cm H₂O, while those for flow triggering are 2 to 3 L per minute. The sensitivity threshold is important because it is required to strike a balance between two main problems associated with triggering. First, if the sensitivity is set too low, patients may experience autotriggering, in which pressure and flow changes that occur from sources of artifact such as cardiac oscillations, water in the circuit, patient movement or resonance within the system leading to irregular breathing patterns and dyssynchrony. Second, sensitivity settings that are too high will lead to ineffective triggering, which has the consequences of increased and wasted work and energy (Fig. 30.10). Ineffective triggering is also common in the setting of dynamic hyperinflation, as seen in obstructive disorders such as asthma and chronic obstructive pulmonary disease. In the setting of obstructive diseases, dynamic hyperinflation leads to elevations in the intrinsic PEEP (PEEP) above a critical threshold such that the patient’s respiratory drive is insufficient to overcome the elastic recoil of the lung and chest wall and trigger the ventilator [50]. Clearly, this is also disadvantageous to the patient in terms of work of breathing and may contribute to ventilator dyssynchrony. Leung et al. [71] demonstrated that ineffective trigger attempts required 38% increases in patient effort as compared to successfully triggered breaths. Obviously, autotriggering and ineffective triggering can create a challenge to the clinician when attempting to optimize the ventilator settings. In general, it is helpful to reduce the trigger threshold to a point where the delay
between neural firing and ventilator support is minimized without allowing autotriggering to occur.

**FIGURE 30.10** This pressure and flow tracing demonstrated failed trigger attempts that can be appreciated by the negative deflections in the expiratory limbs in the flow waveform and delineated by lines A and B.

**Cycle-Off Variable**

Neurons in the respiratory center continue firing beyond ventilator triggering and throughout inspiration. The cessation of firing is an important time point in the respiratory cycle and marks the beginning of expiration. The neural inspiratory time is often variable from breath to breath [50]. This can lead to considerable dyssynchrony in controlled modes of ventilation such as assisted-control, pressure-control, and intermittent mandatory ventilation, where the “cycle-off” variable for the ventilator into expiration is the inspiratory time (T_i) and is generally constant from one breath to the next. This can lead to increased sedation requirements, which are inconsistent with the goal of ventilator weaning, as mentioned earlier. Ideally, the ventilator should be able to detect the end of neural firing and react accordingly to halt the inspiratory pressure supplied. This is one of the goals and advantages of the “supportive” modes of ventilation such as pressure support ventilation.

Supportive modes of ventilation have the ability to detect patient expiration and stop ventilator inspiration such that the T_i is variable. This can be accomplished by measuring flow or pressure changes within the
circuit. As neural firing ceases and $P_{\text{mus}}$ decreases to baseline with muscle relaxation, total pressure and thus flow should decrease according to the elastive and resistive properties of the lung according to the equation of motion previously described. Typically, support modes have software that detects a preset decrement in flow, which in turn leads to cycling off the inspiratory support. This preset threshold can be an absolute value of flow or a percentage of maximum flow in the circuit, or both. Often, an increase in pressure that exceeds the programmed support level will also signal the ventilator to stop inspiration as well as open the expiratory valve.

Just as with triggering, the cycle-off variable can be a source of serious tribulations with the patient–ventilator interaction. For example, in the setting of decreased lung elastance, such as emphysematous lung disease, flow may not diminish enough to be detected properly despite a drop in $P_{\text{mus}}$ at the end of neural inspiratory time. This can lead to patient discomfort and was studied by Jubran et al. [72], who noticed that 5 out of 12 patients with chronic obstructive pulmonary disease required active exhalation to cycle off the ventilator during pressure support ventilation at 20 cm $H_2O$. Active exhalation is counterproductive to both the primary goal of respiratory muscle unloading and ventilator synchrony (Fig. 30.11). Furthermore, active exhalation will decrease transpulmonary pressure, which can lead to premature airway closure and increased intrinsic PEEP as closing capacity increases.

FIGURE 30.11 The pressure and flow waveforms demonstrate active recruitment of expiratory muscles to terminate ventilator inspiration. Note the time point marked by line A in which flow decreases rapidly corresponding to a sharp increase in the airway pressure due to active exhalation.
Inspiratory Flow Variable

Inspiratory flow is now being recognized as an important parameter for assisted modes of ventilation. Critically ill patients in acute respiratory failure often have elevated respiratory drives that appear to demand greater flow to overcome the resistance of the failing respiratory system and ventilator breathing circuit [50]. Classically, this appears as a depression on the inspiratory limb of the airway pressure tracing and has been described by some practitioners as “flow hunger” (Fig. 30.12). Clinically, the response has been to increase flow, which typically ranges between 30 and 80 L per minute during assisted modes of mechanical ventilation in an effort to decrease the work of breathing and intrinsic PEEP in these situations. However, a recent series of studies has shown that this may in fact be counterproductive due to a phenomenon now recognized as “flow-associated tachypnea” [50]. Puddy and Younes [73] demonstrated this phenomenon by adjusting inspiratory flow in awake volunteers breathing on a volume-cycled ventilator in assist-control mode in which inspiratory $T_i$ was variable. Laghi et al. [74] later delineated the contributions of flow, tidal volume, and inspiratory time in their study in which flow was increased from 60 to 90 L per minute and balanced with tidal volume settings of 1.0 and 1.5 L to maintain a constant inspiratory time, where frequency did not change. They were able to show that imposed ventilator inspiratory time during mechanical ventilation can determine frequency independent of delivered inspiratory flow and tidal volume. Therefore, the clinician must consider the counteracting variables of flow, tidal volume, and inspiratory time when attempting to ventilate patients with elevated respiratory drive in acute respiratory failure and how one may negatively influence the other.
FIGURE 30.12 The pressure and flow waveforms above demonstrate the classic depressions on the inspiratory airway (P-air) pressure tracing in a patient with an elevated respiratory drive as highlighted by circle A. P-eso, esophageal pressure.

Neurally Adjusted Ventilator Assist (NAVA)

Thille et al. have shown that as many as 24% of intubated patients undergoing pressure support ventilation had severe asynchrony [75]. Asynchrony increases respiratory muscle load [55] and is associated with longer duration of mechanical ventilation [75,76]. Neurally Adjusted Ventilator Assist (NAVA) is a method of ventilation designed to improve patient comfort and ventilator synchrony. By improving the ventilator synchrony to better correlate with a patient’s neuronal respiratory drive, one could decrease the work of breathing and possibly the duration of mechanical ventilation.

More specifically, NAVA is a pressure-assisted mode of MV, which delivers a pressure proportional to the integral of the electrical activity of the diaphragm (EAdi) recorded continuously through an esophageal probe and therefore is proportional to the neural output of the patient’s central respiratory command [77]. As a result, it depends on the patient’s respiratory center neural output how much pressure is delivered. Correct positioning of the esophageal probe is of paramount importance for obtaining representative EAdi signals from the diaphragm. Barwing et al. found that positioning the EAdi-catheter using a method of measurement from the nose, ear and xiphoid, gives a good approximation of the catheter position in most patients [78].

With NAVA, the ventilator is triggered and cycled-off based on the EAdi value, which directly reflects the activity of the neural respiratory command [79]. The inspiratory airway pressure applied by the ventilator is determined by the following equation:
\[ P_{aw} = \text{NAVA level} \times \text{EAdi} \]

where \( P_{aw} \) is the instantaneous airway pressure (cm H\(_2\)O), EAdi is the instantaneous integral of the diaphragmatic electrical activity signal (\( \mu \text{V} \)), and the NAVA level (cm H\(_2\)O/\( \mu \text{V} \) or per arbitrary unit) is a proportionality constant set by the clinician [79]. NAVA thus has two important features: the delivered pressure is, in theory, synchronous with the diaphragmatic activity and the tidal volume is completely controlled by the output of the patient’s respiratory control center [77]. Therefore, the level of pressure delivered is determined by the patient’s respiratory-center neural output [79].

In a prospective interventional study of spontaneously breathing patients with respiratory failure, Piquilloud et al. compared the inspiratory trigger delay, the excess inspiratory time and the frequency of patient–ventilator asynchrony between 22 patients. Compared with standard pressure support ventilation (PSV), NAVA improved patient–ventilator synchrony by reducing the inspiratory trigger delay and the total number of asynchrony events and by improving expiratory cycling-off [80]. Furthermore, there is good evidence suggesting that NAVA—as compared to PSV—offers protection against excessive \( P_{aw} \) and tidal volume values because there is a downregulation of EAdi in response to increasing assistance levels [80–85].
SUMMARY

Respiratory monitoring is a complicated task for the critically ill patient who requires mechanical ventilation. The clinician must carefully balance a plethora of data acquired from studying variables of gas exchange, pulmonary mechanics, neuromuscular function, and patient–ventilator interactions. Skilled intensive care–trained personnel must then process these data so that a plan of respiratory support, often with mechanical ventilation, can be instituted. This plan must proceed in such a way that the patient is safely ventilated and oxygenated without imposing the undo harm that is associated with injurious modes of mechanical ventilation.

3. Puddy A, Younes M: Effect of inspiratory flow rate on respiratory

Neurologic function is a major determinant of quality of life. Injury or dysfunction can have profound effects on a patient’s ability to be alert, communicate, and interact with his or her environment meaningfully, and function as an independent human being. The brain is a highly complex organ with specialized areas of function and is exquisitely sensitive to metabolic and physical insults such as hypoxemia, acidosis, trauma, and hypoperfusion. The goal of neurocritical care is to protect the brain and preserve neurologic functions for the critically ill patient. The impetus for multimodal monitoring of brain function arises from both its importance and vulnerability and also the difficulty in obtaining a satisfactory assessment of function in the setting of numerous insults and processes including toxic and metabolic encephalopathy, sedation and chemical restraints, and primary central nervous system (CNS) processes like stroke and traumatic brain injury (TBI).

There has been rapid growth and there continues to be much interest in the field as numerous devices and modalities are developed to monitor brain function and processes including intracranial pressure (ICP) monitoring, electroencephalography, corticography, global and regional brain tissue oxygen monitoring, cerebral blood flow (CBF) measurements, and neurochemical and cellular metabolism assessment by microdialysis.

As with any diagnostic or therapeutic tool, an understanding of the indications, limitations, risks and benefits of an intervention are essential in the effective utilization, interpretation, and application of the obtained information to the management of the individual patient. Important characteristics of monitoring devices include the ability to detect important abnormalities (sensitivity), to differentiate between dissimilar disease states (specificity), and to prompt changes in care that alter long-term outcomes (Table 31.1). Limitations of techniques include risks to
patients (during placement, use, and removal), variability errors in
generation of data (e.g., calibration and drift), and inherent trade-offs
between specificity and sensitivity. Monitors with high specificity—values
fall outside of threshold levels only when a disease state is unequivocally
present—are unlikely to detect less profound levels of disease, while
monitors with high sensitivity (will detect any value outside of the normal
range) are likely to demonstrate small deviations from normal, which
may be trivial in individual patients. The advantage of multimodal
monitoring is it increases the sensitivity and accuracy of our detection of
physiologic and cellular changes that signal further impending clinical
deterioration by using different monitoring modalities in a
complementary fashion. A legitimate concern raised by some is that the
vast amounts of data generated by these devices require computer-
supported data analyses that have been costly and time-consuming, may
overwhelm the ill-prepared clinician, and could negate whatever benefits
may be gained from the new technology [1]. Most agree that careful
consideration should go into selecting the appropriate patient to monitor,
the modalities to use, and that determining the most beneficial
application of these technologies requires further prospective study.

p. 269

p. 270
The compelling theoretical importance of brain monitoring is based on the high vulnerability of the brain to hypoxic and ischemic injuries. The brain uses more oxygen and glucose per weight of tissue than any other organ, yet has no appreciable reserves of oxygen or glucose. The brain is thus completely dependent on uninterrupted CBF to supply metabolic substrates that are required for continued function and survival and to remove toxic by-products. Even transient interruptions of CBF, whether local or global, can injure or kill neural cells. These perturbations may not result in immediate cell death, but can initiate metabolic or cellular processes (e.g., gene transcription, secondary injury) that may lead to cell death days, months, or years after the insult. Therefore, clinical monitoring of neuronal well-being should emphasize early detection and reversal of potentially harmful conditions. Although there are limited conclusive data to demonstrate that morbidity and mortality are reduced by the information gathered from current neurologic monitoring techniques, most clinicians caring for patients with critical neurologic illness have confidence that their use improves management. In this chapter, we review currently available techniques with an emphasis on the current scientific literature and indications for utilization.

GOALS OF BRAIN MONITORING

Monitoring devices cannot independently improve outcomes. Instead, they contribute physiologic data that can be integrated into a care plan that, while frequently adding risks (associated with placement, use, and removal), may lead to an overall decrease in morbidity and mortality.

Neurologic monitoring can be categorized into three main groups: (1) monitors of neurologic function (e.g., neurologic examination, electroencephalogram [EEG], evoked potentials, functional magnetic resonance imaging [MRI]), (2) monitors of physiologic parameters (e.g., ICP, CBP, transcranial Doppler), and (3) monitors of cellular metabolism (e.g., jugular venous oxygen saturation [SjvO₂], near-infrared spectroscopy [NIRS], brain tissue oxygen tension, microdialysis, positron emission tomography [PET], magnetic resonance spectroscopy). Most categorizations are arbitrary and obviously overlaps and interrelationships between modalities (e.g., blood flow and electrical activity, oxygenation, and perfusion) blur the lines of distinction. All categories provide information that may be useful in assessing the
current status of the brain and nervous system and in directing therapies as well as monitoring responses to interventions, but it cannot be overemphasized that the data obtained from these monitoring devices should always be interpreted in relation to the overall clinical picture of the individual patient.
CEREBRAL ISCHEMIA AND BLOOD FLOW

Given the brain’s dependence and sensitivity to perturbations of oxygenation, many, if not all, monitors are concerned with the detection of cerebral ischemia defined as cerebral delivery of oxygen (CDO$_2$) insufficient to meet metabolic needs. Cerebral ischemia is traditionally characterized as global or focal, and complete or incomplete (Table 31.2). Systemic monitors readily detect most global cerebral insults, such as hypotension, hypoxemia, or cardiac arrest. Brain-specific monitors can provide additional information primarily for situations, such as stroke, subarachnoid hemorrhage (SAH) with vasospasm, and TBI, for which systemic oxygenation and perfusion can appear to be adequate when focal cerebral oxygenation is impaired.

The severity of ischemic brain damage has traditionally been thought to be proportional to the magnitude and duration of reduced CDO$_2$. For monitoring to influence long-term patient morbidity and mortality, prompt recognition of reversible cerebral hypoxia/ischemia is essential. Numerous animal studies and human studies using different imaging techniques such as PET, MRI, and single-photon emission computed tomography (SPECT) have concluded that the ischemic threshold for reversible injury or penumbra is a CBF of 20 mL/100 g/minute below which tissue is at risk of irreversible damage [2,3]. The tolerable duration of more profound ischemia is inversely proportional to the severity of
CBF reduction (Fig. 31.1). Ischemia and hypoxemia initiate a cascade of cellular reactions that involve multiple pathways including energy failure from anaerobic glycolysis with accumulation of lactic acid and increase in lactate/pyruvate ratios, loss of ion homeostasis and failure of ATP-dependent ion pumps to maintain ion gradients. This leads to sodium and calcium influx into the cell and activation of enzymes such as phospholipases that result in further membrane and cytoskeletal damage, glutamate release and excitotoxicity, lipoperoxidases and free fatty acid breakdown, and free radical formation and inflammation with microvascular changes. Endonucleases which alter gene regulation and protein synthesis and activate the caspase pathways that trigger apoptosis are also released [4,5]. Other proteins synthesized in response to altered oxygen delivery, such as hypoxia-inducible factors, have been identified as adaptive mechanisms that respond to variations in oxygen partial pressure [6] and may be protective. These multiple pathways and cellular mediators and their interactions are potential areas for therapeutic intervention. By-products of these reactions provide potential biomarkers for secondary injury that can be used for monitoring. Our current understanding of how the data is best used is still evolving; and currently, when a cerebral monitor detects ischemia, the results must be carefully interpreted. Often, all that is known is that cerebral oxygenation in the region of the brain that is assessed by that monitor has fallen below a critical threshold. Such information neither definitively implies that ischemia will necessarily progress to infarction nor does it clearly define what biochemical or genetic transcriptional changes may subsequently occur. Also, because more severe ischemia produces neurologic injury more quickly than less severe ischemia, time and dose effects must be considered. More importantly, if regional ischemia involves structures that are not components of the monitored variable, then infarction could develop without warning.
Among healthy persons, CBF is tightly regulated through multiple pathways such that $\text{CDO}_2$ is adjusted to meet the metabolic requirements of the brain. In the normal, “coupled” relationship, CBF is dependent on the cerebral metabolic rate for oxygen ($\text{CMRO}_2$), which varies directly with body temperature and with the level of brain activation (Fig. 31.2A). As $\text{CMRO}_2$ increases or decreases, CBF increases or decreases to match oxygen requirements with oxygen delivery. Pressure autoregulation
maintains CBF at a constant rate (assuming unchanged metabolic needs) over a wide range of systemic blood pressures (Fig. 31.2B). When pressure autoregulation is intact, changes in cerebral perfusion pressure (CPP) do not alter CBF over a range of pressures of 50 to 130 mm Hg. CPP can be described by the equation CPP = MAP – ICP, where MAP equals mean arterial pressure. After neurologic insults (e.g., TBI), autoregulation of the cerebral vasculature may be impaired such that CBF may not increase sufficiently in response to decreasing CPP [7]. This failure to maintain adequate CDO\textsubscript{2} can lead to ischemia and add to preexisting brain injury, a process termed secondary injury, at blood pressures that would not normally be associated with cerebral ischemia/injury. Normally, arterial partial pressure of carbon dioxide (PaCO\textsubscript{2}) significantly regulates cerebral vascular resistance (CVR) over a range of PaCO\textsubscript{2} of 20 to 80 mm Hg (Fig. 31.2C). CBF is acutely halved if PaCO\textsubscript{2} is halved, and doubled if PaCO\textsubscript{2} is doubled. This reduction in CBF (via arteriolar vasoconstriction) results in a decrease in cerebral blood volume and a decrease in ICP. Conceptually, decreasing PaCO\textsubscript{2} to decrease ICP may appear to be desirable. Hyperventilation as a clinical tool was described by Lundberg et al. [8] in 1959 as a treatment for increased ICP and was a mainstay of treatment for over 40 years. However, for the healthy brain, there are limits to maximal cerebral vasoconstriction with falling PaCO\textsubscript{2} (as well as vasodilation with increasing PaCO\textsubscript{2}), such that, as CBF decreases to the point of producing inadequate CDO\textsubscript{2}, local vasodilatory mechanisms tend to restore CBF and CDO\textsubscript{2}. As a consequence, for the healthy brain, hyperventilation does not produce severe cerebral ischemia; however, after TBI, hypocapnia can generate cerebral ischemia as reflected by decreased partial pressure of brain tissue oxygen concentration (PbtO\textsubscript{2}) and SjvO\textsubscript{2} [9,10]. For this reason, hyperventilation has fallen out of favor as a treatment modality for intracranial hypertension and is only used as an immediate intervention to bridge a patient to emergent definitive surgery such as decompressive craniectomy or removal of an offending mass lesion. If hyperventilation is required to acutely reduce ICP, administration of an increased inspired oxygen concentration can markedly increase SjvO\textsubscript{2} (Fig. 31.3). In response to decreasing arterial oxygen content (CaO\textsubscript{2}), whether the reduction is secondary to a decrease in hemoglobin (Hgb) concentration or in arterial oxygen saturation (SaO\textsubscript{2}), CBF normally increases, although injured brain tissue has impaired ability to increase CBF when it lacks autoregulation [11].
FIGURE 31.2 A: The normal relationship between the cerebral metabolic rate of oxygen consumption (CMRO₂) and cerebral blood flow (CBF) is characterized by closely coupled changes in both variables. Normally, CBF is 50 mL/100 g/min in adults (open triangle). As CMRO₂ increases or decreases, CBF changes in a parallel fashion (solid line). B: Effect of mean arterial pressure (MAP) on CBF. Note that changes in MAP produce little change in CBF over a broad range of pressures. If intracranial pressure (ICP) exceeds normal limits, substitute cerebral perfusion pressure on the horizontal axis. C: Effect of PaCO₂ on CBF. Changes in PaCO₂ exert powerful effects on cerebral vascular resistance across the entire clinically applicable range of values.

FIGURE 31.3 The effect of hyperoxia on percentage of oxygen saturation of jugular venous blood (SjvO₂) at two levels of PaCO₂. *p < 0.001 for SjvO₂ at PaCO₂ 25 to 30 mm Hg at each PaO₂. †p < 0.001 for SjvO₂ between PaO₂ at each PaCO₂ level.
TECHNIQUES OF NEUROLOGIC MONITORING

Neurologic Examination

Frequent and accurately recorded neurologic examinations are an essential aspect of medical care, but are often limited among patients with moderate to severe neurologic compromise. Neurologic examination quantifies three key characteristics: level of consciousness, focal brain dysfunction, and trends in neurologic function. Recognition of changing consciousness or new focal deficits may warn of a variety of treatable conditions, such as progression of intracranial hypertension, new mass lesions such as expansion of intraparenchymal contusions or subdural hematoma and systemic complications of intracranial pathology, such as hyponatremia.

The Glasgow Coma Scale (GCS) score, originally developed as a tool for the assessment of impaired consciousness [12], has also been used as a prognostic tool for patients with TBI [13]. The GCS score at the time of initial hospitalization is used to characterize the severity of TBI, with severe TBI defined as a GCS score less than or equal to 8, moderate TBI as a GCS score of 9 to 12, and mild TBI as that associated with a GCS score greater than 12. Lower GCS scores are generally associated with poorer long-term outcomes, although correlation to individual patients with TBI is complicated by the significant variations of mortality rates and functional outcomes [14]. Significant concern has arisen regarding the validity of the initial GCS score on presentation given the aggressive prehospital management of these patients over the last decade or so, that includes sedation and intubation in the field or the administration of paralytics and sedatives in the emergency room. Some authors have reported a loss of predictive value of the GCS score from 1997 onward and call for a critical reconsideration of its use [15]. Other studies have looked at GCS in the field versus GCS upon arrival and have found good correlation and prognostic value for predicting outcomes and have even found the changes in scores from field GCS to arrival GCS to be highly predictive of outcomes for patients with moderate to severe TBI [16].

Many centers use the best GCS or postresuscitation GCS during the first 24 hours or just the motor component of the GCS instead of initial GCS given these issues. Nevertheless, the GCS score is popular as a quick, reproducible estimate of level of consciousness (Table 31.3). It is a common tool for the serial monitoring of consciousness, and has been incorporated into various outcome models, such as the Trauma score,
Acute Physiology and Chronic Health Evaluation (APACHE), and the Trauma-Injury Severity score. The GCS score, which includes eye opening, motor responses in the best functioning limb, and verbal responses, is limited and by no means replaces a thoughtful and focused neurologic examination. It should be supplemented by recording pupillary size and reactivity, cranial nerve examination, and more detailed neurologic testing depending on the relevant neuroanatomy involved in the disease process. Given the limitations of assessing the GCS, particularly the verbal score in intubated patients, a mathematical model was developed to estimate the verbal score based on the eye and motor scores and is currently being utilized by some stroke trials but needs further validation [17]. A more comprehensive coma assessment score was formulated by Wijdicks and colleagues called the Full Outline of UnResponsiveness or FOUR Score. This removes the verbal score altogether, includes assessments of command following nonverbally, expands the eye assessment to include tracking, blinking to threat and blinking to command, incorporates brainstem function assessments of pupillary and corneal reflexes as well as breathing patterns, and has been validated in multiple populations of critically ill patients and been found to have good prognostic value [18] (Fig. 31.4).

FIGURE 31.4 Description of Full Outline of UnResponsiveness (FOUR) Score. Eye response: E4, eyelids open or opened, tracking, or blinking to command; E3, eyelids open but not tracking; E2, eyelids closed but open to loud voice; E1, eyelids closed but open to pain; E0, eyelids remain closed with pain. Motor response: M4, thumbs-up, fist, or peace sign; M3, localizing to pain; M2, flexion response to pain; M1, extension response to pain; M0, no response.
to pain or generalized myoclonus status. Brainstem reflexes: B4, pupil and corneal reflexes present; B3, one pupil wide and fixed; B2, pupil or corneal reflexes absent; B1, pupil and corneal reflexes absent; B0, absent pupil, corneal, and cough reflex. Respiration pattern: R4, not intubated, regular breathing pattern; R3, not intubated, Cheyne–Stokes breathing pattern; R2, not intubated, irregular breathing; R1, breathes above ventilatory rate; R0, breathes at ventilator rate or apnea.

Systemic Monitoring

Although not specific to neurologic monitoring, systemic parameters, including blood pressure, SaO$_2$, PaCO$_2$, serum glucose concentration, and temperature, have clinical relevance in the management of patients with neurologic dysfunction or injury. The relationships between these systemic variables and long-term outcome after neurologic insults are closely linked and are subject to continuing research.

Perhaps the most important systemic monitor is blood pressure, as CBF is dependent on the relationship between CPP and CVR, and can be modeled generally by the equation: $\text{CBF} = \text{CPP}/\text{CVR}$. As discussed previously, CBF is maintained relatively constant over a wide range of blood pressures (pressure autoregulation) through arteriolar changes in resistance (assuming no change in brain metabolism) in healthy individuals. After brain injury, autoregulation may become impaired, especially in traumatically brain-injured patients. Chesnut et al. [19,20] reported that even brief periods of hypotension (systolic blood pressure less than 90 mm Hg) worsened outcomes after TBI, and recommended that systolic blood pressure be maintained greater than 90 mm Hg (with possible benefit from higher pressures) [21]. These recommendations have also been promoted by the Brain Trauma Foundation for patients with severe TBI [22]. To achieve this goal, the use of vasoactive substances, such as norepinephrine, may be required [23]. Nevertheless, optimal blood pressure management for patients with TBI has yet to be defined. Some clinical data suggest that the influence of hypotension on outcomes after TBI is equivalent to the influence of hypotension on outcomes after non-neurologic trauma [24]. Current proposed treatment protocols often recommend CPP greater than 50 to 70 mm Hg [25]. The augmentation of CPP above 70 mm Hg with fluids and vasopressors has, however, been associated with increased risk of acute respiratory distress syndrome (ARDS) and is not universally recommended [25]. CPP goals need to be formulated with concomitant assessments of ICP, regional oxygenation and electrical-metabolic brain activity, and cerebral autoregulation.

Another essential step in insuring adequate CDO$_2$ is the maintenance
of adequate CaO₂, which in turn is dependent on Hgb and SaO₂; therefore, anemia and hypoxemia can reduce CDO₂, which would normally result in compensatory increases in CBF. However, these compensatory mechanisms are limited. As SaO₂ (or PaO₂) decreases below the compensatory threshold, SjvO₂ and jugular venous oxygen content (CjvO₂), which reflect the ability of CDO₂ to supply CMRO₂, also decrease. The correlation is most evident below a PaO₂ of approximately 60 mm Hg, the PaO₂ at which SaO₂ is 90% and below which SaO₂ rapidly decreases. In contrast, as Hgb is reduced by normovolemic hemodilution, SjvO₂ remains relatively constant unless severe anemia is present [26].

The management of arterial CO₂ for patients with neurologic injury has changed dramatically during the past 10 years. Although hyperventilation as a management strategy for increased ICP was routine in the 1990s, it is now reserved for acute or life-threatening increases in the intensive care unit (ICU) and is no longer recommended for routine use. Having been associated with cerebral ischemia of children and adults [9,10] with severe TBI, hyperventilation is least likely to be harmful when combined with monitoring, such as SjvO₂ or PbtO₂, that can identify cerebral ischemia.

Hyperglycemia increased injury during experimental TBI [28] and was associated with worse outcomes for clinical TBI [29,30], although it is difficult to distinguish between elevated glucose causing worsened outcome versus increased severity of TBI inducing more elevated glucose levels [30]. Among critically ill patients requiring mechanical ventilation, elevated glucose levels were associated with worsened outcomes [31], and current recommendations are tight serum glucose control for critically ill patients in the medical and surgical ICU [32]. Caution must be exercised in the brain-injured patient as there is also evidence to suggest that hypoglycemia can be more detrimental than hyperglycemia, and microdialysis studies of TBI patients found that extracellular glucose concentration was low after TBI and associated with markers for tissue distress and poor outcomes [33].

The monitoring and management of body temperature remains an important aspect of care for critically ill patients. Hypothermia and hyperthermia should be considered separately in this context. The use of hypothermia as a treatment for brain injury, while demonstrating benefits for animal models [34] and for some phase 2 human studies, has
not shown consistent benefit in larger studies [35] and is not recommended for general use in TBI [36,37]. Several randomized clinical trials have had disappointing results and failed to show functional outcome benefits or reduction in mortality. [38,39] Issues and concerns that have arisen from these trials include whether there was proper management of the side effects of hypothermia and rewarming, questions about the timing and duration of therapy, the optimal target temperature and the heterogeneity and size of the patient population studied [40,41]. Subgroup analysis of NABISH-2 suggests that there may be benefits for TBI with patients with evacuated mass lesions such as subdural hematomas [42,43] and an ongoing multicenter trial has been started to determine if rapid induction of hypothermia prior to emergent craniotomy for subdural hematoma will improve outcomes as measured by Glasgow Outcome Scale-Extended (GOSE) at 6 months [44]. In contrast, induced hypothermia after resuscitation from cardiac arrest (secondary to ventricular tachycardia or fibrillation) has improved outcomes of some trials [45,46].

Hyperthermia is common among critically ill patients, occurring in up to 90% of patients with neurologic disease, related to both diagnosis and length of stay [47,48]. Hyperthermia is generally associated with poorer outcomes when associated with neurologic injury of adults and children [49], but direct evidence for a causal link with adverse outcomes (as with serum glucose levels) is lacking. It is unclear whether increased temperatures result in worsened long-term neurologic outcomes, or whether a greater severity of brain injury is associated with more frequent or severe increases in systemic temperature.

The method of temperature monitoring is important. Thermal gradients exist throughout the body, and the site of measurement influences the diagnosis of hypothermia, normothermia, or hyperthermia. Measurements of systemic temperature may underestimate brain temperature. In studies of temperature monitoring by site, variations of up to 3°C have been identified between the brain and other routinely used monitoring sites, emphasizing the importance of monitoring site selection for patients with neurologic injury and the need to appreciate the difference between brain temperature and the active site of measurement used clinically for a given patient.

EEG/Electrocorticography

Electroencephalographic (EEG) monitoring has long been used in neurology for diagnosis and intraoperative monitoring, but has less frequently been used as a neurologic monitoring technique for critically ill patients. EEG is indicated in response to suspicion of a new or progressive abnormality such as cerebral ischemia or new onset of
seizures. The cortical EEG or electrocorticography, which is altered by mild cerebral ischemia and abolished by profound cerebral ischemia, can be used to indicate potentially damaging cerebral hypoperfusion. More recent research has documented its utility for the detection of cortical spreading depression and peri-infarct and posttraumatic depolarizations which are thought to be early indicators of delayed ischemic injury of the acutely injured human cortex after TBI, SAH, malignant ischemic stroke, or intracerebral hemorrhage [50–53]. The EEG can document seizures, either convulsive or nonconvulsive, and provide information as to the efficacy of antiseizure therapy. Other functions include defining the depth or type of coma, documenting focal or lateralizing intracranial abnormalities, and supporting the diagnosis of brain death.

When the EEG is to be used for monitoring, care must be taken and weaknesses of the technique appreciated. In the ICU, electrical noise from other equipment may produce artifacts and interfere with technically adequate tracings. Continuous EEG recording was cumbersome in the past owing to the sheer volume of data (300 pages per hour of hard copy on as many as 16 channels), but techniques for digital recording and networking direct computer recording of EEG data are now available given adequate computer power and storage. Scalp fixation has also been a significant limiting factor, although newer fixation techniques are easier to apply and more stable. Techniques of mathematical data analysis, such as rapid Fourier analysis, can be used to determine the relative amplitude in each frequency band (σ—less than 4 Hz, θ—4 to 8 Hz, α—8 to 13 Hz, β—greater than 13 Hz), which can then be displayed graphically in formats such as the compressed spectral array or density spectral array [54]. Alpha variability and the delta to alpha ratio has been found to predict vasospasm/delayed cerebral ischemia in SAH patients [55], and the percentage of alpha variability was found to have prognostic value for TBI patients [56,57]. Analytical software has been developed that processes the raw EEG signal to provide single number interpretation of the “depth of sedation.” These devices have been recommended for use during general anesthesia as a means to reduce the risk of awareness [58], although the scientific justification for this claim is not conclusive. The American Society of Anesthesiologists has developed a practice advisory on this issue [59]. Use of this type of monitoring has also been implemented by some for use in the ICU for monitoring sedation levels of the critically ill, the utility of which has yet to be proven [60,61]. All devices use proprietary analyses of an EEG signal (either spontaneous or evoked, with or without electromyogram monitoring), which is converted to a single number that is intended to correspond to an awareness level based on an arbitrary scale. The role and evidence of improved patient outcomes with this monitoring modality is undergoing further study and development as well as efforts
to standardize reporting, facilitate multicenter collaborative research and improve applicability [62,63]. A more detailed discussion of the clinical indications, technical aspects, and limitations can be found in recent reviews [64,65].

Evoked Potentials

Sensory evoked potentials (EPs), which include somatosensory EPs (SSEPs), brainstem auditory EPs (BAEPs), and visual EPs (VEPs), can be used as qualitative threshold monitors to detect severe neural ischemia and injury and test the integrity of structures and connections between the CNS (e.g., brainstem and cortex) and the peripheral nervous system. Unlike EEG that records the continuous, spontaneous activity of the brain, EPs evaluate the responses of the brain to specific stimuli. To record SSEPs, stimuli are applied to a peripheral nerve, usually the median nerve at the wrist or posterior tibial nerve at the ankle, by a low-amplitude current of approximately 20 ms in duration. The resultant sensory (afferent) nerve stimulation and resultant cortical response to the stimulus are recorded at the scalp. Repeated identical stimuli are applied and signal averaging is used to remove the highly variable background EEG and other environmental electrical noise and thereby visualize reproducible evoked responses (Fig. 31.5).

FIGURE 31.5 Averaging reduces background noise. After 100 trials, this visual evoked potential (EP) is relatively noise-free. The same EP is hard to distinguish after only 10 trials and would be impossible to find in the original unaveraged data.
EPs are described in terms of the amplitude of cortical response peaks and the conduction delay (latency) between the stimulus and the appearance of response waveform. Because peripheral nerve stimulation can be uncomfortable, SSEPs are usually obtained from sedated or anesthetized patients. SSEPs are unaffected by neuromuscular blocking agents but may be significantly influenced by sedative, analgesic, and anesthetic agents, often in a dose-dependent manner. In general, however, the doses of drugs required to influence EPs are sufficient to produce general anesthesia and are not usually clinically important in the ICU. If a patient is undergoing EP monitoring and requires large doses of analgesic or sedative agents, potential impairment of monitoring should be considered. Motor EPs represent a method of selectively evaluating descending motor tracts. Stimulation of proximal motor tracts (cortical or spinal) and evaluation of subsequent responses yield information that can be used for intraoperative and early postoperative neurosurgical management. Induction of motor EP and its interpretation is exquisitely sensitive to sedative, analgesic, and anesthetic drugs, making clinical use difficult when drugs are given concurrently. Despite these limitations, motor EP evaluation has been used successfully for the management of neuro-ICU patients and may become more common as techniques and equipment evolve [66,67].

Likewise, BAEPs and VEPs utilize auditory and visual sensory stimulation and record responses to them from the auditory and visual cortices and test the integrity of connections to and from them to the periphery.

The sensitivity of EP monitoring is similar to that of EEG monitoring. EPs, especially BAEPs, are relatively robust, although they can be modified by trauma, hypoxia, or ischemia. Because obliteration of EPs occurs only under conditions of profound cerebral ischemia or mechanical trauma, EP monitoring is one of the most specific ways in which to assess neurologic integrity of specific monitored pathways. However, as with the discussion of cerebral ischemia, there is a dose–time interaction that ultimately determines the magnitude of cerebral injury. As a result, neurologic deficits occur that have not been predicted by changes in EPs, and severe changes in EPs may not be followed by neurologic deficits. The most definitive indication for SSEPs is in the prognostication of anoxic brain injury after cardiac arrest. The absence of the N20 response on bilateral SSEPs of the median nerve within 3 days
postarrest has been found to be a reliable predictor of negative outcome or recovery of consciousness for anoxic postarrest coma and is part of the American Academy of Neurology (AAN) practice parameter in the prognostication of postanoxic coma [68]. Different EPs have been studied after anoxia, TBI, coma as well as brain death, and have been found to have prognostic value to varying degrees. Various reviews and consensus statements have been published that provide specific indications and criteria [69,70].

**Intracranial Pressure Monitoring**

The symptoms and signs of intracranial hypertension are neither sensitive nor specific. Usually, the physical findings associated with increasing ICP (e.g., Cushing’s response–hypertension and Cushing’s triad–hypertension, reflex bradycardia, and alterations in respiratory function) become apparent only when intracranial hypertension has become sufficiently severe to injure the brain. Likewise, papilledema is a late development and is often difficult to identify clinically. Because ICP cannot otherwise be adequately assessed, direct measurement and monitoring of ICP has become a common intervention, especially in the management of TBI [71], and less commonly after critical illnesses such as SAH or stroke. Although there is no level 1 evidence that the use of this technique improves outcomes, there is a large body of clinical evidence supporting its use to guide therapeutic interventions after TBI that have potential risks (such as aggressive osmotherapy, induced hypothermia, and barbiturate coma), to aid with the detection of intracranial mass lesions and to provide prognostic data [72]. ICP monitoring has been found to improve outcome prediction after TBI and next to clinical parameters such as age, GCS motor score, and abnormal pupillary responses, the proportion of hourly ICP recordings greater than 20 mm Hg was the next most robust predictor of outcomes in an analysis done of the National Traumatic Coma Data Bank [73]. Based on these data, the Brain Trauma Foundation/American Association of Neurosurgeons Guidelines recommend ICP monitoring for all patients with severe TBI (GCS < 8) and an abnormal CT scan or a normal scan with patients who are greater than 40 years old, have motor posturing, or a systolic BP <90 mm Hg [74,75]. This guideline is controversial however because it was not based on randomized trial data. Moreover, a recent multicenter randomized clinical trial comparing an ICP monitoring-driven treatment regimen to one without ICP monitoring performed in South America (because of the lack of clinical equipoise in the United States) demonstrated no benefits of monitoring and controlling ICP <20 mm Hg. This trial has only added to the controversy of ICP monitoring [76].

ICP functions as the outflow pressure apposing MAP (CPP = MAP –
ICP) when ICP exceeds jugular venous pressure. Because the skull is not distensible, the brain, cerebrospinal fluid (CSF), and cerebral blood volume have little room to expand without increasing ICP. It is important to appreciate that some increase in intracranial volume is possible without much change in ICP, but when the compensatory mechanisms are exhausted, even small changes in volume can lead to significant increases in pressure. Although CBF cannot be directly inferred from knowledge of MAP and ICP, severe increases in ICP reduce CPP and CBF. ICP monitoring provides temporally relevant, quantitative information. The problems associated with ICP monitoring fall generally into three categories: direct morbidity due to monitor placement (e.g., intracranial hemorrhage, cortical damage, and infections), inaccurate measurement, and misinterpretation or inappropriate use of the data. Clinically, only two sites are used to measure ICP: a lateral ventricle with an external ventricular drain (EVD) or the surface of the brain with an intraparenchymal monitor. Ventricular catheterization, when performed using strict aseptic technique, is the method of choice for ICP monitoring and CSF drainage in patients with acute intracranial hypertension and excess CSF (i.e., acute hydrocephalus). In practice, intraventricular catheters may be difficult to place if cerebral edema or brain swelling has compressed the ventricular system. Intraventricular pressure monitoring can also be performed with fiberoptic catheters (instead of a hollow catheter) that use a variable reflectance pressure sensing system (transducer tip) to measure pressure (Camino Laboratories, San Diego, CA). These fiberoptic catheters are less susceptible to short-term malfunction than conventional, fluid-filled catheters but may slowly and unpredictably drift over days to weeks [77].

Previously used monitors include subdural ICP monitors such as a fluid-coupled bolt (simple transcranial conduit), fluid-coupled subdural catheters (or reservoirs), or fiberoptic transducer-tipped catheters have fallen out of use because of technical issues with fixation and reliability and complications such as the possibility of brain tissue herniating into the system, obstructing the system, distorting measurements, and potentially damaging the cerebral cortex including causing subdural hematomas.

Intraparenchymal placement of a fiberoptic catheter is also possible and is associated with complications similar to ventricular fiberoptic catheters. Complications are generally noted to be highest with ventriculostomies (when compared with fiberoptic catheter usage), and complications of ICP monitoring are associated with a worse GCS score.

The interpretation and utility of ICP readings from EVDs and intraparenchymal monitors are subject to numerous limitations. First, the monitors are often single monitors placed in a specific region of the brain parenchyma (often the right frontal lobe as it is non-eloquent
cortex that will not result in neurologic dysfunction) usually in or adjacent to the most severely damaged hemisphere [78]. Because of this, however, it only reflects pressure in one region of the brain. There are pressure gradients that exist among various sites within the calvarium, and the pressure in the middle cranial fossa and posterior cranial fossa may not be reflected by ICP readings from the right frontal lobe and it is possible for patients to have middle cranial or inferior cranial fossa herniation without ICP elevations. For this reason, some have recommended bilateral or multiple ICP monitors be placed to circumvent this problem [79]. This is not practical and significantly increases the risk of the procedure and many neurosurgeons would oppose this. Even EVDs, although placed in the lateral ventricle and considered the gold standard for measuring ICP, can be misleading in the presence of posterior cranial fossa pressure. Shift and mass effect as well as hydrocephalus and significant clinical herniation can occur immediately prior to or without ICP elevations in certain situations. As with any monitoring device, clinical examination and interpretation in light of synthesis of all the other data is essential.

Management decisions based on ICP data continue to be the focus of ongoing debate and study. Previous clinical studies after TBI had demonstrated that increased ICP was associated with worse outcome [80]. Therefore, control of ICP had been considered by some clinicians to be the primary focus of treatment [22], while other clinicians considered restoration of CPP (by increasing MAP) to be the primary goal of medical management [81]. Although there was a possible suggestion of improved neurologic outcomes with cerebral perfusion-driven protocols, the problem was there were also more complications including ARDS [82].

All the data and trials investigating ICP and its effects on brain physiology after TBI had previously been non-randomized and II to III level of evidence. Given the lack of clinical equipoise, a clinical trial could not be done in the United States. Chesnut and colleagues conducted a multicenter controlled trial in Bolivia and Ecuador, of 324 severe TBI patients who were being treated in the ICU and randomly assigned them to either an ICP-driven treatment protocol which utilized ICP monitors and treated ICP greater than 20 mm Hg or a protocol of treatment based on clinical examination and serial imaging [76]. The primary outcome was a composite measure of survival time, impaired consciousness, functional outcome at 3 and 6 months, and neuropsychologic status at 6 months. There were no differences among the groups in terms of functional outcomes, mortality, or length of stay. The ICP monitoring group had fewer days of brain-specific treatments such as osmotherapy but did have more frequent administration of barbiturates or hypertonic saline. Given that there were no ICP measurements in the control group, a true comparison of the impact of the ICPs is difficult to conclude. This
study did further emphasize that clinical assessments continue to be an important evaluation of brain function for which we have no current adequate substitute, as well as a conceptual problem of thinking that summed pressures as measured by ICP monitors will always be increased in the setting of mechanical tissue displacements that occur regionally in the brain and skull [83]. Rather than resulting in the abandonment of this monitoring modality, this study has reemphasized the need for clinical and imaging assessments and changed the way that ICP is utilized in that the cutoff value of 20 mm Hg is no longer an absolute goal. Many were not surprised with the results of this study given the now better understood complexity of the pathophysiology of TBI with multiple clinical and physiologic factors and numerous secondary injury pathways possibly influencing neurologic function and clinical outcomes. ICP monitoring continues to be utilized; but many intensivists have revised their protocols to include more nuanced assessments of pressure, including cerebral perfusion and assessments of autoregulation as well as other modalities such as regional and global oxygenation [84]. Figure 31.6 is an example.

Cerebral Blood Flow Monitoring

The first quantitative clinical method of measurement of CBF, the Kety–Schmidt technique, calculated global CBF from the difference between the arterial and jugular bulb concentration curves of an inhaled, inert gas as it equilibrated with blood and brain tissue. Later techniques used extracranial $\gamma$ detectors to measure regional cortical CBF from washout curves after intracarotid injection of a radioisotope such as 133-xenon (Xe 133). Carotid puncture was avoided by techniques that measured cortical CBF after inhaled or intravenous administration of Xe 133, using $\gamma$ counting of exhaled gas to correct clearance curves for recirculation of Xe 133. Because Xe is radiodense, saturation of brain tissue increases radiographic density in proportion to CBF. Imaging of the brain after equilibration with stable (nonradioactive) Xe provides a regional estimate of CBF that includes deep brain structures. Clinical studies of CBF after TBI performed using stable xenon computed tomography (CT) have prompted a radical revision of conventional understanding by demonstrating that one-third of patients had evidence of cerebral ischemia within 8 hours of trauma. Although slow in becoming a routine clinical tool, Xe CT is becoming a more common technique for monitoring CBF in patients. The use of helical and spiral CT scanners (with very short acquisition times) reduces radiation exposure to the patient and decreases the time needed for a scan, improving clinical utility [85]. A newer method of measuring CBF that provides continuous bedside quantitative measurements is the thermal diffusion technique. This consists of the insertion of a microprobe into the brain parenchyma with a thermistor at the tip and a temperature sensor proximal to it. The thermistor is heated to 2° above tissue temperature and CBF is calculated using the thermal gradient and provides a quantified regional CBF measurement in mL/100 g/minute. Some studies suggest a correlation with regional brain tissue oxygenation and a possible role for guiding management of ICP. Technical issues such as the invasive nature of the device, frequent calibration, and the limitations seen among febrile patients have kept this method from becoming more widely adopted [86]. Another CT-based technique, perfusion CT, uses iodinated contrast infusion with repeated images to calculate local CBF. This technique is limited to smaller regions and may not provide uniform results between brain regions [87]. Other techniques, such as SPECT and magnetic resonance perfusion imaging, also can provide information about CBF, but their clinical utility is still under study.

Transcranial Doppler Ultrasound

Transcranial Doppler ultrasonography can be used to estimate changes in
CBF. For most patients, cerebral arterial flow velocity in intracranial vessels can be measured easily, especially the middle cerebral artery, using transcranial Doppler ultrasonography. Doppler flow velocity uses the frequency shift, proportional to velocity, which is observed when sound waves are reflected from moving red blood cells. Blood moving toward the transducer shifts the transmitted frequency to higher frequencies; blood moving away, to lower frequencies. Velocity is a function of both blood flow rate and vessel diameter. When diameter remains constant, changes in velocity are proportional to changes in CBF; however, intersubject differences in flow velocity correlate poorly with intersubject differences in CBF. Entirely noninvasive, transcranial Doppler measurements can be repeated at frequent intervals or even applied continuously. The detection and monitoring of post-SAH vasospasm remains the most common use of transcranial Doppler ([Fig. 31.7] [88]). However, further clinical research is necessary to define those situations for which the excellent capacity for rapid trend monitoring can be exploited, including assessment of vascular autoregulation, ancillary testing to detect intracranial hypertension, and brain death.

**FIGURE 31.7** Mean flow velocity (FV, in cm/s) curves of 18 patients with laterally localized aneurysms (arising from the internal carotid and middle cerebral arteries). The side of the ruptured aneurysm (continuous line) shows a higher FV than the unaffected side (dotted line). SAH, subarachnoid hemorrhage.

Jugular Venous Bulb Oxygen Saturation

Several measurements of cerebral oxygenation are clinically useful, including measurement of SjvO\(_2\). To insert a retrograde jugular venous bulb catheter, the internal jugular vein can be located by ultrasound guidance or by external anatomic landmarks and use of a “seeker” needle, namely, the same technique used for antegrade placement of jugular venous catheters. Once the vessel is identified, the catheter is directed cephalad, toward the mastoid process, instead of centrally. A lateral cranial radiograph can confirm the position just superior to the base of the skull. The decision to place a jugular bulb catheter in the left or right jugular bulb is important. Simultaneous measurements of SjvO\(_2\) in the right and left jugular bulb demonstrate differences in saturation [89], suggesting that one jugular bulb frequently is dominant, carrying the greater portion of cerebral venous blood. Differences in the cross-sectional areas of the vessels that form the torcula and the manner in which blood is distributed to the right and left lateral sinus contribute to differences between the two jugular bulbs. Ideally, a jugular bulb catheter should be placed on the dominant side, which can be identified as the jugular vein that, if compressed, produces the greater increase in ICP or as the vein on the side of the larger jugular foramen as detected by CT [90].

In general, SjvO\(_2\) reflects the adequacy of CDO\(_2\) to support CMRO\(_2\), but mixed cerebral venous blood, like mixed systemic blood, represents a global average of cerebral venous blood from regions that are variably perfused and may not reflect marked regional hypoperfusion/ischemia of small regions. In contrast to ICP and CPP, which provide only indirect information concerning the adequacy of CDO\(_2\) to support CMRO\(_2\), SjvO\(_2\) directly reflects the balance between these variables on a global or hemispheric level. CBF, CMRO\(_2\), CaO\(_2\), and CjvO\(_2\) are modeled by the equation: CMRO\(_2\) = CBF (CaO\(_2\)–CjvO\(_2\)). For a healthy brain, if CMRO\(_2\) remains constant as CBF decreases, SjvO\(_2\) and CjvO\(_2\) decrease [25]. If flow-metabolism coupling is intact, decreases in CMRO\(_2\) result in parallel decreases in CBF while SjvO\(_2\) and CjvO\(_2\) remain constant [25]. Abnormally low SjvO\(_2\) (i.e., less than 50%, compared to a normal value of 65%) suggests the possibility of cerebral ischemia, but normal or elevated SjvO\(_2\) does not prove the adequacy of cerebral perfusion because of possible saturation averaging between normal and abnormal areas of perfusion. This is especially true for focal areas of hypoperfusion.
Therefore, the negative predictive value of a normal SjvO\textsubscript{2} is poor. After placement of a jugular catheter, monitoring of SjvO\textsubscript{2} can be achieved through repeated blood sampling. However, repeated blood sampling yields only “snapshots” of cerebral oxygenation and thus provides discontinuous data that may miss rapid changes in saturation. To achieve continuous monitoring of SjvO\textsubscript{2}, indwelling fiberoptic oximetric catheters have been used. Because oxyhemoglobin and deoxyhemoglobin absorb light differently, SjvO\textsubscript{2} can be determined from differential absorbance. Oximetric jugular bulb catheters have proven somewhat challenging to maintain, requiring frequent recalibration, repositioning, and confirmation of measured saturation by analyzing blood samples in a CO-oximeter. The highest frequency of confirmed desaturation episodes occurs in patients with intracerebral hematomas, closely followed by those with SAH. For patients with TBI, the number of jugular desaturations is strongly associated with poor neurologic outcome; even a single desaturation episode is associated with a doubling of the mortality rate [91]. Clinical application of jugular venous bulb cannulation has been limited, perhaps in part because the technique is invasive, although the risks of cannulation injury, including hematoma and injury to the adjacent carotid, are low. Several modifications of jugular venous oxygen monitoring have been proposed. Cerebral extraction of oxygen, which is the difference between SaO\textsubscript{2} and SjvO\textsubscript{2} divided by SaO\textsubscript{2}, is less confounded by anemia than the cerebral A-VDO\textsubscript{2} [92]. Another concept, termed cerebral hemodynamic reserve, is defined as the ratio of percentage of change in global cerebral extraction of oxygen (reflecting the balance between CMRO\textsubscript{2} and CBF) to percentage of change in CPP. This equation attempts to integrate cerebral hemodynamics and metabolism with intracranial compliance. Cruz et al. [92] found that cerebral hemodynamic reserve decreased as intracranial compliance decreased, even as a consequence of minor elevations in ICP. Theoretically, this variable may allow more precise management of cerebral hemodynamics in patients with decreased intracranial compliance.

**Brain Tissue Oxygen Tension**

Another promising technique for monitoring the adequacy of CDO\textsubscript{2} is direct assessment of brain tissue oxygen tension or PbtO\textsubscript{2}. Monitoring of PbtO\textsubscript{2} overcomes one important limitation of SjvO\textsubscript{2} monitoring, which is that the global saturation measurements provide no information about regional or focal tissue oxygenation. Only relatively profound focal global
ischemia causes SjvO$_2$ to decrease to less than the accepted critical threshold of 50%. Even severe regional ischemia may not result in desaturation if venous effluent from other regions is normally saturated, in part because the absolute flow of poorly saturated blood returning from ischemic regions is by definition less per volume of tissue than flow from well-perfused regions, resulting in a smaller percentage of poorly oxygenated to well-oxygenated blood. Intracranial, intraparenchymal probes have been developed that monitor only PbtO$_2$ or that also monitor brain tissue PCO$_2$ and pH [93]. Modified from probes designed for continuous monitoring of arterial blood gases, intraparenchymal probes can be inserted through multiple-lumen ICP monitoring bolts. Although these probes provide no information about remote regions, they nevertheless provide continuous information about the region that is contiguous to the probe. They also carry the theoretical risks of hematoma formation, infection, and direct parenchymal injury. Evaluation of PbtO$_2$ after severe TBI has shown that low partial pressures (PbtO$_2$ less than 10 mm Hg for greater than 15 minutes) powerfully predict poor outcomes and that PbtO$_2$ probes are safe [94,95]. Both PbtO$_2$ and SjvO$_2$ may reflect changes in cerebral oxygenation secondary to alterations in CBF (Fig. 31.8) [96]. However, comparisons of simultaneous PbtO$_2$ and SjvO$_2$ monitoring suggest that each monitor detects cerebral ischemia that the other fails to detect. In 58 patients with severe TBI, the two monitors detected 52 episodes in which SjvO$_2$ decreased to less than 50% or PbtO$_2$ decreased to less than 8 mm Hg; of those 52 episodes, both monitored variables fell below the ischemic threshold in 17, only SjvO$_2$ reflected ischemia in 19, and only PbtO$_2$ reflected ischemia in 16 (Fig. 31.9) [97]. There have been eight completed studies comparing ICP/CPP-guided therapy to PbtO$_2$ + ICP/CPP-driven protocols, six retrospective studies, and two prospective studies in severe TBI patients, and results have been mixed. One study showed worse functional independence measures at discharge, three showed no benefit looking at GOS scores at 6 months and mortality at discharge, two showed reduced mortality at discharge and at 3 months, and two showed a trend toward better outcome or better outcome as measured by GOS at 3 and 6 months, respectively. The studies are nicely summarized and thoughtfully discussed in a review by DeGeorgia [98]. Preliminary results of the ongoing phase 2 randomized multicenter clinical trial investigating the safety and efficacy of brain tissue oxygen monitoring in severe TBI (BOOST-2) were presented at the Neurocritical Care Society meeting in October 2014. Patients aged 14 years and older with severe nonpenetrating TBI were randomized to treatment with ICP monitoring
alone or with ICP and PbtO₂ monitoring which showed no differences in adverse events and safety but also met non-futility measures with lower overall mortality and lower poor outcome in the ICP and PbtO₂-monitored group. Initial conclusions were that a TBI treatment protocol guided by ICP and PbtO₂ reduced the duration of measured brain tissue hypoxia and was relatively safe [99]. The findings of this study will be used to determine the phase 3 study sample size [100].

* FIGURE 31.8 The effect of hyperventilation-induced hypocapnia on changes in mean arterial blood pressure (MABP), intracranial pressure (ICP), cerebral perfusion pressure (CPP), end-tidal CO₂ (ETCO₂), PtiO₂, and jugular bulb oximetry (SjvO₂). *p < 0.05; before hyperventilation versus 10 min later.

Neurochemical Monitoring

Neuronal injury is associated with the release or production of chemical markers such as free radicals, inflammatory mediators, metabolic products, and excitatory amino acids [4]. Neurochemical monitoring via microdialysis allows assessment of the chemical milieu of cerebral extracellular fluid, provides valuable information about neurochemical processes in various neuropathologic states, and is used clinically in the management of severe TBI [101] and SAH [102,103]. There are data to suggest that chemical changes detected by microdialysis precede secondary neurologic injury and clinical worsening for intracranial hypertension, SAH, and ischemic stroke patients. Substances monitored via microdialysis include energy-related metabolites such as glucose,
lactate, pyruvate, adenosine, and xanthine; neurotransmitters such as glutamate, aspartate, γ -amino butyric acid; markers of tissue damage such as glycerol and potassium [104], and alterations in membrane phospholipids by oxygen radicals [105]. Lactate levels and lactate/pyruvate ratios are reliable markers of ischemia and have been found to correlate well with PET, CPP, and jugular venous bulb oxygen saturation values, and associated with outcomes after TBI and SAH. Elevations of the excitatory neurotransmitter glutamate have been found after hypoxic-ischemic injury seen in low CBF, jugular venous bulb desaturation, seizures and low CPP, and correlated with poor outcomes following TBI. The magnitude of release of these substances correlates with the extent of ischemic damage. The time-dependent changes in these substances and the clinical implications are being evaluated, and their incorporation into standard practice is being studied. Certain issues related to quantification, bedside presentation of data, implantation strategies, and standardization of protocols need to be addressed. An excellent review of the current status, issues surrounding potential future developments, and methodological aspects of microdialysis are discussed in detail in an article by Hillered and colleagues [106].

Near-Infrared Spectroscopy

Theoretically, the best monitor of brain oxygenation would be a noninvasive device that characterizes brain oxygenation in real time: NIRS might eventually offer the opportunity to assess the adequacy of brain oxygenation continuously and noninvasively, although to date the use of the technique in adults has been limited.

Near-infrared light penetrates the skull and, during transmission through or reflection from brain tissue, undergoes changes in intensity that are proportional to the relative concentrations of oxygenated and deoxygenated hemoglobin in the arteries, capillaries, and veins within the field [107]. The absorption (A) of light by a chromophore (i.e., hemoglobin) is defined by Beer’s law: $A = abc$, where $a$ is the absorption constant, $b$ is the path length of the light, and $c$ is the concentration of the chromophore, namely, oxygenated and deoxygenated hemoglobin. Because it is impossible to measure the path length of NIRS light in tissue, approximations as to relative lengths and arterial versus venous contribution must be made.

Extensive preclinical and clinical data demonstrate that NIRS detects qualitative changes in brain oxygenation [108]. Studies have been done comparing NIRS to other technologies and assessing its correlation with EEG, transcranial Doppler, PbtO₂, and jugular venous O₂ saturation changes. NIRS was found to correlate with EEG, TCD, and PtO₂ during transient cerebral hypoxia, after SAH, and during intraoperative
monitoring for carotid endarterectomy. It did not correlate well with SjvO$_2$ [109] values but was thought to provide complementary focal oxygenation data to SjvO$_2$’s global oxygenation assessment. Clinical applications include TBI where an rSO$_2$ of less than 55% was thought to suggest inadequate CPP and NIRS values were lower for the high ICP group of patients vasospasm detection in the setting of SAH, and the detection of intracranial hemorrhages such as subdural and epidural hematomas but studies are not definitive [110]. Despite the promise and enthusiasm generated by NIRS, many problems remain with the technology including tissue penetration, spatial and temporal resolution, artifacts from subcutaneous blood flow and methods of quantitative analysis which need to be resolved [111]. Therefore, validation studies suggest that NIRS may be more useful for qualitatively monitoring trends in brain tissue oxygenation than for actual quantification and its current clinical use is limited to a few centers and is adjunctive at best [108,112]. Some of the liabilities of NIRS may be overcome by optoacoustic monitoring of cerebral venous saturation. Optoacoustic monitoring of cerebral venous saturation depends on the generation by near-infrared light of ultrasonic signals in blood. The acoustic signals are then transmitted linearly through tissue and bone, and provide a focused, depth-resolved signal that reflects venous oxygenation [113].

**Neuroimaging**

MRI, PET scans, cerebral angiography, and radionuclide scans do not function as monitors per se. Rather, they are indicated in response to suspicion of a new or progressive anatomic lesion, such as a subdural or intracerebral hematoma or cerebral arterial vasospasm, that requires altered treatment. Most neuroimaging modalities provide static, discontinuous data and require moving a critically ill patient from the ICU to a remote location. Even so, these techniques play an important role in the overall management of patients with brain injury [114]. With the introduction of portable CT scanners and the development of ultrafast helical and spiral CT scanners, availability and acquisition time for evaluations have significantly decreased and can now be used for serial monitoring of ongoing neurologic processes and for evaluation of changes in CBF (see above).

CT scans obtained at the time of admission to the hospital can provide valuable prognostic information. Marshall et al. [115] predicted outcome of head-injured patients in relation to four grades of increasingly severe diffuse brain injury and the presence of evacuated or nonevacuated intracranial mass lesions (Table 31.4). Normal CT scans at admission in patients with GCS scores less than 8 are associated with a 10% to 15% incidence of ICP elevation [116,117]; however, the risk of ICP elevation
increases for patients older than age 40 years, those with unilateral or bilateral motor posturing, or those with systolic blood pressure less than 90 mm Hg [116].

Although MRI often provides better resolution than CT scans, the powerful magnetic fields make the use of ferrous metals impractical (and dangerous), a ubiquitous component of life-support equipment. To address this issue, MRI-compatible ventilators, monitors, and infusion pumps have been developed, although the logistics of transport and the time required for scans continues to make this technique difficult for repeated monitoring. Recent advances in MRI technology, such as diffusion-weighted imaging, magnetic resonance spectroscopy (carbon labeled, phosphorus labeled, and nitrogen labeled), phase-contrast angiography, and functional MRI provide information about oxidative metabolic pathways, cerebral blood volume, functional CBF, and neuronal activation [114,118,119]. These techniques, while undergoing further evaluation and validation, may 1 day prove useful for evaluating brain injury and guiding its management. Recent clinical evidence of brain mitochondrial dysfunction after TBI, despite apparently adequate CDO$_2$, suggests that functional cellular evaluation and associated therapy
may someday be as important as maintaining CDO₂ [120]. In addition to providing information regarding ischemia and defining tissue at risk, MRI-based diffusion tensor imaging has been found to be helpful for further defining the anatomy of fiber tracts that have been damaged and has also been found to have prognostic value after severe TBI [121]. Functional MRI provides information regarding neural activity, localization, and the physiology of brain function but is currently in use only for neurosurgical planning, brain mapping, and in the investigation of neurobehavioral aspects and neuropsychologic sequelae of disorders such as Alzheimer’s disease, stroke, multiple sclerosis, brain tumors, and TBI.
MULTIMODAL MONITORING STRATEGIES

With technological advances and active ongoing research, the field of neurologic monitoring is developing rapidly. Multimodal monitoring takes into account the limitations of each monitoring modality and compensates by combining different techniques into a generalized strategy that help to further elucidate the pathophysiology and underlying cellular mechanisms of disease and focuses care on the physiologic aspects of disease. This concept is not new (consider the operating room and the role of the anesthesiologist) and is becoming more common in the management of brain injury [122] as well as other neurologic diseases. There are multiple modalities with data to support their use but also issues with each modality (Table 31.5). Currently, there is multidisciplinary consensus on the use of multimodal monitoring strategies from various societies who endorse it as an important feature of neurocritical care but do raise concerns about the amount of data generated and emphasize the need for integration and synthesis of all relevant clinical data in the care of the individual patient. It is anticipated that further research and developments in technology, interfaces, database infrastructure, and bioinformatics as well as further elucidation of meaningful, normative, and validated data will improve the utility of monitoring devices and lead to improvements in therapeutics and patient outcomes [123,124].

NEW FORMS OF ELECTRONIC SUPPORT FOR CRITICAL CARE PROFESSIONALS

The challenge of delivering critical care medicine in the 21st century has become increasingly clear, and there is broad consensus for making safe and effective care more available by controlling costs. This challenge is multifactorial and consists of several well-documented elements including a growing number of critically ill patients [1,2], an aging population [3], an unprecedented focus on accountable care and reducing healthcare spending [4], an inadequate number and maldistribution of qualified critical care providers [5–8], and public expectations for patient safety and the reduction of medical errors [9]. Ongoing efforts continue to center on finding evidence-based approaches to these complex and competing factors. One approach to solving the current challenges is “Telemedicine,” defined as the application of communications and information technologies to allow specialty-trained physicians to care for patients remotely. This chapter will explore the rationale, advantages, and limitations associated with using telemedicine to care for critically ill patients under the current challenges facing healthcare.

Most proponents of healthcare improvement advocate ideas and solutions that can be encapsulated by the Institute for Healthcare Improvement’s Triple Aim [10]. As health systems develop or transform, the Triple Aim provides a framework centered on three cornerstones that are simultaneously pursued—improving the quality and satisfaction of the patient care experience, improving the health of populations, and
reducing the per capita cost of healthcare. The choices surrounding how to deliver critical care are important because both spending and mortality in the critical care setting are the highest for all of healthcare [11]. Annually, almost 6 million Americans are admitted to one of the 6,300 intensive care units (ICUs) located in 3,200 acute care hospitals, where 55,000 patients receive ICU care every day [12–14]. Recent evidence shows that from 2000 to 2009, the number of hospital beds did not grow substantially likely owing to the shift of healthcare to the outpatient setting. However, there was a substantial increase in the number of ICU beds, signifying a trend that a growing proportion of hospital operations are focused on the care of the critically ill [2]. Annually, these patients have required intensive care that contributes up to $100 billion of the over $3 trillion spent on all of US healthcare, corresponding to about 1% of the gross domestic product (GDP) [15]. In comparison, other countries spend as little as 0.1% of their GDP on critical care without appreciable differences in patient outcomes or life expectancy [16]. Further evidence shows that 25% of all US healthcare spending is in the final year of life and that approximately 20% of deaths occur in or soon after an ICU stay [17].

The combination of the post-World War II population expansion, known as the “baby boom,” and the increase in life expectancy for US adults has led to large increases in older segments of our population that have required more critical care services [3,18]. By 2030, it is estimated that over 70 million US residents will be over 65, an age group that currently requires three times as much critical care resources as that of younger groups of patients. In addition, patients 85 years and older require six times as much critical care, and the size of this age group is projected to triple by 2030 compared with the 2006 population. The challenge associated with this expansion is compounded by the increasing focus on patient and family-centered care, which is the assurance that clinical care decisions are guided by the values and preferences of individual patients and their loved ones [19]. Healthcare information technology as a means to access healthcare is increasingly preferred by patients because it combines convenience with the ability to connect to specialists and other providers in ways that meet their expectations, which have traditionally been largely unmet [20]. These issues have spawned efforts by health policy experts and administrators to find solutions to increase the quality and efficiency of critical care delivery. The integration of telecommunications technologies and health information system data is allowing telemedicine to become an increasingly important part of the healthcare delivery system [21].
The increased need for critical care and the high costs associated with caring for critically ill adults have led to an intense interest in practical methods for increasing the efficiency of critical care delivery. A growing body of literature indicates that care delivered by intensive care–trained professionals can increase quality and improve important outcomes such as lowering mortality and length of stay (LOS) [22,23]. Healthcare payers, both governmental and private, are shifting payment models from traditional fee-for-service to value-based reimbursement systems [4]. Accordingly, hospitals and healthcare organizations are beginning to focus on quality standards and increased efficiency as the backbone of their delivery models as opposed to simply increasing the volume of services provided. One of the largest advocates in patient safety and quality has been The Leapfrog Group, a nonprofit organization and consortium of Fortune 500 companies that has established measures of improvement for all of healthcare [24]. Leapfrog compliance has continued to be a priority for hospitals and includes intensivist staffing as one of its key measures, or “leaps.” The Leapfrog standard requires intensivists to be dedicated exclusively to providing care in the ICU during daytime hours [14]. If intensivists are unavailable, Leapfrog states that they must be reachable within 5 minutes and arrange for specifically trained nonintensivists, including nonphysicians, to reach the patient within 5 minutes. These initiatives are based on broadly accepted evidence that intensivist-led ICU teams can lower mortality, lower LOS, and increase quality [25]. However, less than one-quarter of ICUs in Leapfrog’s recent surveys meet the intensivist staffing marker [26], a failure and an indicator of the broad difficulty of providing ICU patients healthcare by dedicated, specialty-trained, and certified providers. Interestingly, as telemedicine delivery models have grown, The Leapfrog Group has identified tele-intensivist programs as compliant with their standards [27], thus indicating strong support of ICU telemedicine programs as a leveraging technology that provides a practical way to deliver high-quality critical care.

Termed a “crisis,” many critical care societies have publicly acknowledged the growing discrepancy between the supply of intensivists and the demand for critical care [28]. The etiology of this shortage is multifactorial and includes an inadequate growth of ICU fellowship and graduate medical education (GME) training programs [6], decreased interest in critical care as a career [29,30], and high rates of physicians leaving the field before retirement age [31]. In addition, not all qualified providers spend the majority of their time in the critical care setting because most ICU professionals trained in pulmonary medicine, anesthesiology, neurology, or surgery practice critical care as only part of their careers [32]. The simplest strategy to address this supply shortage is to produce more intensivists by increasing the number of GME training...
positions [7,33]. However, this strategy would increase costs by adding to the more than $15 billion currently spent on GME, which comes directly out of the US healthcare budget [34,35]. Furthermore, it could have unintended consequences on other areas of healthcare that are also thought to have an inadequate number of qualified providers [36]. The critical care physician shortage also has an element of maldistribution because there are a disproportionately larger number of critical care specialists in urban hospital ICUs than in rural areas [37]. Critical care is delivered throughout the United States in a variety of settings, but the majority of ICU beds are located in nonteaching community hospitals with fewer than 300 beds [14]. A critically ill patient with access to an ICU, unfortunately, does not uniformly indicate high quality and comprehensive care because wide variation exists in when and how critical care specialists, if available, provide care [38]. Furthermore, critical illnesses such as sepsis, acute respiratory distress syndrome, acute coronary syndrome, acute cerebrovascular accidents, and venous thromboembolism require timely standardized intervention delivered by healthcare teams comprised of individuals with adequate recent experience to maintain proficiency. Telemedicine support can increase the frequency of high-quality care at locations that would have otherwise delayed care in view of the need to transport patients to locations with qualified providers. ICU telemedicine programs have the potential to reduce mortality in diseases that require early goal-directed care, reduce costs associated with transport, and allow tertiary care hospitals to manage higher acuity cases that require services that are not available locally. ICU telemedicine programs also have the potential to improve access to high-quality care at community hospitals that are closer to the patient’s home.

Importantly, simply increasing the number of intensivists might not solve the maldistribution issue because most qualified providers prefer to work in urban and suburban areas, whereas most ICUs without intensivists are in rural areas [39]. In addition, with limited numbers of providers at a particular location, it remains difficult for hospitals to retain intensivists owing in part to the increased workload and inadequate staffing and inadequate night and weekend coverage for their ICUs [40]. The US Health Resources and Services Administration (HRSA) recently projected a workforce gap of over 3,300 intensivist full-time equivalents by 2020 [6]. Well-intended strategies to solve this supply matrix crisis include increasing the training and distribution of advanced practice providers (APPs), either physician assistants (PA) or nurse practitioners (NP) [41]. More than 200,000 NPs and more than 90,000 PAs are currently practicing in the United States [42,43]. However, less than half of these providers are educated and trained in acute and critical care, including only 4,000 NPs who are actively
working in critical care environments [44]. While intensivists often provide care in ratios of 1:12 and above, APPs often provide care in ratios of 1:4–5. To date, this approach has not provided an adequate supply of critical care providers to solve the workforce demand.

Government funding, through the creation of the Affordable Care Act [45], has recently initiated funding for healthcare innovation ideas across the full spectrum of healthcare delivery. One such example includes a financially successful initiative that integrates specific critical care training with APPs along with telemedicine oversight by intensivists to serve the high demand for ICU care professionals in underserved areas [46]. In addition to the federal government, state appropriations and foundation grants have similarly appropriated funds to technology-based innovation in telehealth with the common theme of improving access to high-quality care.

Telemedicine integration into ICU healthcare delivery helps solve the supply problem because it removes geographic barriers to high-quality care, thus increasing the number of ICU patients that can receive evaluation and management services from a critical care specialist–led team. Intensivist-led tele-ICU teams can serve a substantially larger population of patients than intensivists using traditional telephonic tools [47,48]. This is due in part to the use of dedicated workstations that run software designed to collect and display clinical information in a format that allows more efficient management of critically ill adults. These workstations include bidirectional audio/video, clinical decision support, population management software, and smart alarms and alerts that allow earlier detection of physiologic instability and abnormal laboratory values. They are also designed to support the efficient recording of provider orders and care protocols. These tools allow increased provider productivity based on the ability of the technology to collect real-time clinical data from the bedside and display electronic signatures of care need to off-site providers. The effectiveness of this approach depends on the timing and effectiveness of the delivery of evaluation and management services by the ICU telemedicine team [49]. Proactive critical care interventions coupled with provider documentation facilitated by technology such as alarms, alerts, and real-time reporting tools can create a more efficient and effective ICU delivery workflow than the traditional daily time-based rounding and documentation carried out by bedside providers. The optimal number of patients that one tele-intensivist should be responsible for is not well established and would vary widely depending on a variety of factors including local resources, ICU acuity, and telemedicine staffing and support structure [50]. In addition to increasing the number of patients who are able to receive care from a critical care specialist, more community-based ICUs can retain an intensivist because ICU telemedicine practice models reduce off-shift
Some healthcare experts have not only proposed solutions to the issue with supply of ICU providers, but have emphasized potential measures to reduce the demand for ICU care [52]. Although standard ICU admission criteria exist, significant variability in ICU admission practices occurs that can lead to overutilization of resources, increased costs, increased LOS, and more frequent preventable complications [53]. It seems clear that admission to an ICU, either urban or rural, is currently based not on standardized criteria but rather on a variety of factors that often do not reflect the patient’s potential for physiologic instability. Patients with borderline indications for ICU admission often get admitted to the ICU owing to the uncertainty regarding potential deterioration and thus receive more costly care that is unnecessary. An investigation of a large database of ICU admissions showed that only two-thirds of patients admitted to an ICU received an ICU-level intervention [54]. Similarly, less than 40% of patients in another ICU population received mechanical ventilation at any time during their ICU stay [55]. There is wide variation in the way ICUs are used in the United States, and hospitals that tend to use more critical care resources have not shown improved outcomes [56]. Telecommunications and health information technology including bidirectional audio/video, electronic monitoring, and clinical decision support can exist in acute care environments outside of the ICUs to augment in-hospital clinical teams and make better use of constrained resources with tools available to focus on best practices, sepsis management, pain management, readmission risk, and fall prevention. This electronic oversight captures physiologic data and alerts dedicated off-site clinical teams of potential patient deterioration and the need for escalation to ICU-level care through early detection, resulting in the ability to more appropriately utilize costly ICU resources.

Innovative critical care delivery models are gaining attention with the intention to provide safe, timely, consistent, and effective care with a limited number of qualified providers. In this chapter, we will focus on providing the evidence that supports the utilization of telemedicine support systems as a potential innovative technology solution by reengineering the flow of clinical information from the patient to their ICU provider (Fig. 32.1). These tools allow critical care specialists to obtain real-time actionable clinical information and provide evaluation and management services. Connecting to critically ill patients in this way can improve outcomes, lower complications, and increase patient and family satisfaction [57]. Utilizing remote workstations equipped with the
necessary technology, tele-ICU teams consisting of intensivists, APPs, and critical care–certified nurses can provide high-quality critical care where and when it is needed.

FIGURE 32.1 Contrasting traditional intensive care unit (ICU) flow of clinical information with a reengineered workflow utilizing electronic support tools to provide remote qualified ICU professionals with the ability to provide more timely care led by an intensive care physician specialist across a larger ICU population. NP, nurse practitioners; PA, physician assistants.
ICUs continue to evolve in parallel with the rapid maturation of health information technologies. In addition, major advances in the field of critical care medicine have produced meaningful improvements in patient survival. However, the penetration of these advances has been limited by inefficiencies of critical care delivery due to ineffective design or lack of qualified specialists [58]. Remote real-time support for acutely ill patients is a promising strategy that can improve the efficiency of critical care delivery by reengineering the interface between the patient and the ICU care delivery system [59]. Widespread acceptance of healthcare technology into certain healthcare delivery processes has been slow because a period of diffusion of innovation is followed by rapid expansion based on social acceptance [60]. Rapid expansion of technology and mobile communications has heightened societal expectations regarding the ability to access information anywhere, anytime, on personal electronic devices. Convenient access to healthcare is increasingly demanded, and delivery models have not fully integrated available technologies that can reduce inefficiencies, enhance the quality of care, and improve the patient experience. Telemedicine has the potential to provide an on-demand experience that can enhance the patient and family-centered care in ICUs by allowing easier access to desired providers. Interactions with families in ICUs are frequent and important because critically ill patients are often unable to directly participate in complex discussions of diagnosis, prognosis, treatment options, and end-of-life preferences [61]. Because families often rate communication with providers as being as important as clinical skill [62], telecommunication technologies can allow families access to these valuable discussions without being present at the bedside. Anywhere, anytime connectivity can enhance integration of families into the process of critical care delivery, provide an improved family experience during an often stressful time, and reduce overutilization of invasive treatments of little clinical benefit.

Over 100 years ago, attempts at electrocardiogram transmission over telephone lines allowed real-time off-site interpretation [63]. Telemedicine integration into ICU care occurred in the latter half of the past century [64], but the first comprehensive ICU telemedicine program was not implemented until 2000 in Virginia [65]. Wider acceptance did not occur until just over 10 years ago when investigators at Johns Hopkins showed acuity-adjusted improvements in both ICU and hospital mortality based on a continuous intensivist-led tele-ICU care model for two adult ICUs [66]. The tele-ICU platform used in this investigation has
remained the dominant infrastructure and design of tele-ICU delivery to date, although expansion of technologic capabilities and alternative platforms has evolved. Most believe this initial model of continuous telemedicine delivery of intensivist care was the impetus for the growth of the field of ICU telemedicine.

Since the first program installation and the associated patient safety and efficiency of care benefits, there has been growth of programs with similar designs. Based on recent evidence attempting to quantify the expansion of tele-ICU programs in the United States, five integrated tele-ICU programs had been implemented in hospitals prior to 2003 [67]. Adoption of ICU telemedicine occurred in 218 hospitals between 2003 and 2010, an average annual increase of approximately 60%. Within this expansion, the number of ICU beds involved in tele-ICU delivery grew almost 50% per year from 598 to 5,799, while the number of dedicated support centers with tele-ICU professionals grew beyond 40 with wide geographic dispersion across the United States. With expanding technologies, increasing numbers of vendors, and a better understanding of the variation of designs that could potentially meet the needs of the full spectrum of urban and rural hospitals, further growth and saturation is anticipated. An estimated 15% of nonfederal hospital ICU beds in the United States are currently receiving support from a continuous ICU telemedicine model of care [38]. Recent expansion of alternative technology platforms, mobile telecommunications, and episodic care models suggests that the number of ICU patients receiving telemedicine support is larger than the number of closed model bedside intensivist-led ICUs [68].

With regard to design and infrastructure, ICU telemedicine capabilities have broadened in recent years (Table 32.1). Recent literature provides a detailed report of various ways to utilize telemedicine support systems for the care of critically ill patients [48,69,70]. Based on supportive literature, most new ICU telemedicine systems are based on a single design consisting of a centralized support center and provide a continuous model of care with a closed communication architecture. A centralized, closed model consists of a monitoring center—housed by varying staffing models of intensivists, APPs, RNs, and support staff—with sophisticated computer workstations that utilize high-speed communication lines that securely and reliably link multiple hospitals to a central location. This platform provides bidirectional audio/visual capabilities, real-time interfacing and trending of physiologic data, connections to clinical information systems, and audio video connections to patients. A closed “hub and spoke” model generally indicates that providers outside of the monitoring center, such as subspecialists, would not have access to the tele-ICU system and could only provide patient care utilizing traditional modes of communication and data review. In
contrast to a centralized closed architecture, a decentralized “virtual hub” offers open access to tele-ICU team members regardless of their geographic location. An open architecture generally indicates Internet connectivity linking multiple providers from multiple sites to multiple ICUs. In addition, open access allows the ICU telemedicine program to offer virtual subspecialty care to patients, with providers such as cardiologists and neurologists able to access the tele-ICU system from their secure personal devices. ICU telemedicine programs can be structured in ways to provide continuous or episodic care. Continuous care provides the tele-ICU team with the ability to deliver 24/7 critical care management using near real-time responses to electronic signatures of evolving physiologic instability. A discontinuous, or episodic, care model consists of a tele-ICU patient assessment only during designated times either scheduled or requested at the discretion of a bedside clinician. Incorporating various aspects of all the elements of tele-ICU design can create hybrid systems that can facilitate high-quality multispecialty care to critically ill patients in a timely and effective manner [48]. Comparative trials of alternative systems have not been performed in part because systems that meet current telecommunications industry standards have sufficient speed and capacity to achieve nearly equivalent performance.

### TABLE 32.1 ICU Telemedicine Delivery Models [128]

1. Continuous Care Model—Proactive care that occurs on a 24/7 continuous basis servicing an ICU population utilizing a centralized operational center staffed by a team of ICU professionals led by a qualified intensive care physician specialist.

2. Episodic Care Model—Proactive care that occurs intermittently connecting patient–provider or provider–provider on a predetermined basis (e.g., daily rounds) or at unscheduled times.

3. Responsive Care Model—Reactive care, when virtual consults are prompted by an alert (e.g., patient alarm, telephone call).

ICU, intensive care unit.
Since the introduction of the first tele-ICU system, technology and equipment have involved advanced workstations that allow the simultaneous display of data from multiple sources that can allow users to view information from more than one patient at a time. One key safety element is how the systems are designed to assure that a given intervention is prescribed to the patient for which it is intended. Tele-ICU monitoring centers often colocate workstations that include multiple computers, multiple monitor displays, microphones, speakers, and broadband capabilities for teams of providers. This creates efficiency because intensivists can leverage nurses and prescribing APP partners (NP or PA) to complete and document tasks. This tiered and shared strategy allows one intensivist to provide urgent evaluation and management services to as many as 150 critically ill adults.

ICU patient rooms include fixed high-resolution cameras with pan, tilt, and zoom capabilities along with speakers, a microphone, and a display monitor. In addition to the networking architecture, portable and mobile solutions have emerged for both ends of the system. Mobility implies Internet connectivity because intensivists and other involved providers can use an Internet-capable laptop or mobile device to gain access to a private viewing environment. Furthermore, mobile systems are often made available on carts equipped with audio/visual and networking equipment, including some robotic systems that do not require transportation or activation by bedside providers. As innovation continues, mobility and functionality are expected to expand.

The availability of sophisticated technology for the delivery of critical care alone does not improve performance [71]. Maximizing ICU telemedicine effectiveness requires a comprehensive understanding of the determinants of improved clinical and financial outcomes for its optimal application. More is now known about how ICU telemedicine reduces mortality and LOS. A multicenter trial that measured an alternative process of care identified several factors that are associated with greater reductions in mortality and LOS [72]. Early intensivist involvement in the form of workstation-assisted care plan reviews, more rapid responses to alerts and alarms for evolving physiologic instability, interdisciplinary collaboration, high rates of adherence to ICU best practices, and near real-time review of ICU performance data by a leadership team that takes action were associated with lower mortality and shorter LOS. Another study of the ability of off-site nurse reviews and communication to the bedside team reported significantly improved adherence to best practices [73]. Each of the elements that were associated with improved outcomes is concordant with the safety and clinical engineering literature. Studies to date have not identified a particular type or size of ICU that predicts improved outcomes. The approach to improving outcomes may depend less on the type or size of
the ICU and more on the ability of a particular approach and system to impact these key processes in the environment in which it is deployed.

Telemedicine infrastructure can allow intensivist-led teams to provide critical care expertise across a large population of patients through workflow optimization and the efficient and effective use of near real-time analyses of trending clinical information. Without technology support systems, a bedside nurse or provider must recognize and interpret complex and dynamic physiologic and clinical data before action can occur. Relying upon human recognition and interpretation in an ICU environment can produce delay and error [59]. During critical illness, vital signs, laboratory data, imaging results, and medical equipment can produce hundreds of variables occurring simultaneously. Excessive and error-prone medical device alarms in the ICU environment can cause ICU staff mental fatigue (so-called “alarm fatigue”), often resulting in desensitization and delayed response with potential negative impacts on clinical outcomes and patient safety [74–76]. Based on current design, bedside nurses and providers are often multitasking and responding to unpredictable events elsewhere with the ability to interpret only a small fraction of the myriad of clinical information produced [77]. Further delay can occur if an ICU professional is not readily available to provide an intervention or has yet to become engaged in the patient’s care. Current bedside delivery often involves provider rounding and a series of individual evaluations at single points in time. This evaluation includes assessment of current biosensor and clinical information but often does not include tools to detect concerning trends of these factors that can predict deviation from the intended trajectory [78]. ICU telemedicine can provide earlier intervention by ICU professionals along with integration into modern comprehensive patient monitoring systems that enable acquisition, storage, and pattern recognition of the large amounts of patient-specific data. Acquired, organized, and stored data with pattern recognition technology transmitted instantaneously to a tele-ICU can expedite care by enabling earlier recognition of often subtle changes in patient pathophysiology, transitioning from reactive care to proactive and predictive care. With additional connectivity and interoperability among multiple bedside medical devices, such as mechanical ventilators and infusion pumps, complex interactions between patients and therapies can be acquired and interpreted utilizing electronic support [79]. In addition, these systems allow qualified experts to interpret radiographic and ultrasonographic images in near real time. Real-time tele-ICU support for ultrasonography can also improve the quality of acquired images. Clinical decision support system integration further assists the ICU professional in tailoring interventions to the underlying disease process in near real time [80]. Ultimately, an integrated critical care informatics architecture can include real-time
acquisition and storage of all raw clinical data that can be stored, processed, and translated into actionable information to be used by a remote ICU professional to provide management services in a more efficient manner across a larger population of patients [81].
DATA AND OUTCOMES

Clinical Outcomes and Process Measures

As evidence accrues (Table 32.2), it has become more established what particular aspects of critical care delivery are associated with meaningful improvements in outcomes. Significant effort has been placed on attempts to determine the impact of bedside intensivist staffing on patient outcomes. Access to intensivists in high intensity settings has been associated with reductions in both ICU and hospital mortality. This was most recently observed in a meta-analysis including 52 composite studies that showed high intensity staffing was associated with lower ICU mortality (risk ratio = 0.81; 95% confidence interval (CI), 0.68–0.96), lower hospital mortality (risk ratio = 0.83; 95% CI, 0.70–0.99), reduced ICU LOS (−0.38 days, 95% CI, −0.55 to −0.20 days), and reduced hospital LOS (−0.17 days, 95% CI, −0.31 to −0.03 days) [22]. The additional support of 24-hour in-hospital intensivist coverage did not improve ICU or hospital mortality, which is consistent with a majority of studies [82–84]. The inability of 24/7 intensivist models to provide incremental benefits is an important concept for the current paradigm of scarce critical care resources. Not only are nighttime intensivists costly to hospital systems, this model reduces the number of intensivists available for other ICUs competing for an already inadequate supply. Furthermore, findings from recent studies suggest that the presence of an intensivist at the bedside is not as important as when and how an intensivist is involved in patient care [85]. Engagement using telemedicine support tools that ensure earlier intensivist involvement, more timely response to physiologic instability, and improved adherence to best practices was shown to improve outcomes in both high- and low-intensity bedside staffing models similarly.

ICU, intensive care unit; LOS, length of stay; NR, not reported.

*APACHE III (Acute Physiology and Chronic Health Evaluation)—Rosenfield, Breslow, Morrison, Lilly
The ICU telemedicine evidence base has grown such that there are now two meta-analyses available [86,87] to determine the exact clinical and financial impact of telemedicine on critical care. Initially, most of the data revolving around tele-ICU implementation were reports in the non-peer-reviewed literature. However, two influential early studies [65,66] that are thought to have sparked the growth of the tele-ICU field were published in peer-reviewed critical care literature. In 2000, a tele-ICU program installed at a 10-bed community hospital ICU was shown to reduce the severity-adjusted ICU mortality by 45%, hospital mortality and LOS by 30%, and costs by 16% [65]. Subsequently, a 2004 study from two integrated ICUs showed significant improvement in outcomes, including a 26% reduction in overall hospital and ICU mortality, a 16% reduction in LOS, and a 25% reduction in variable costs generating a greater than $3 million financial benefit in the 6-month study period [66]. A common theme of the implementations of these ICU telemedicine programs was collaboration of bedside and tele-ICU intensivists to provide the same quality of care 24/7.

Tele-ICU implementations that use collaborative governance to standardize key processes of critical care delivery have been associated with lower LOS and improved financial performance. Implementations that do not address competitive tendencies of bedside and tele-ICU physicians or allow inexperienced trainees to staff the ICU telemedicine support center have not been associated with significant improvements in performance. In 2009, a large multicenter study of six ICUs did not detect significant associations between tele-ICU implementation and severity-adjusted ICU or hospital mortality, LOS, or rates of complications [88]. Similarly, in 2010, a study from four ICUs in two community hospitals including over 4,000 unit stays failed to detect a reduction in mortality, LOS, or costs after implementation of an ICU telemedicine program [89]. A recent meta-analysis of published data concluded that ICU telemedicine was associated with a reduced risk of ICU mortality (RR 0.79; 95% CI, 0.65–0.96), a reduced risk of hospital mortality (RR 0.83; 95% CI, 0.73–0.94), shorter ICU LOS (−0.62 days; 95% CI, −1.21 to −0.04 days), and shorter hospital LOS (−1.26 days; 95% CI, −2.49 to −0.03 days) [87]. Notably, there was wide variation and poor characterization of the intervention characteristics and processes, making it difficult to identify the aspects of the intervention that were associated with improved performance. Proactive care by tele-intensivists is thought to be one of the hallmarks of positive outcomes in more recent studies. Published in 2012, a retrospective observational study of over 24,000 patients observed significant reductions in both LOS and mortality over a
3-year postimplementation period [90]. Tele-intensivists were encouraged to be proactive in their participation with the patient care plan, and bedside providers were offered various levels of preferred tele-ICU involvement. Severity-adjusted hospital LOS was lowered from 11.86 days (95% CI, 11.52–12.21) to 10.16 days (95% CI, 9.80–10.53), ICU LOS was lowered from 4.35 days (95% CI, 4.22–4.49) to 3.80 days (95% CI, 3.65–3.94), and the relative risk of hospital mortality decreased to 0.77 (95% CI, 0.69–0.87). However, in 2014, contrary results were published with a US Department of Veterans Affairs healthcare system where no outcome benefit was shown regarding the impact of tele-ICU on hospital LOS or ICU, hospital, and 30-day mortality [91]. The authors did note significant variability among ICUs in their readiness to adopt and implement tele-ICU. Also, the extraordinary low baseline mortality rate reduced the statistical power, thus making it difficult to establish significance regarding the outcomes studied.

In 2011, a study provided more detailed descriptions of the intervention and included analyses that related changes in process to changes in outcomes [92]. A collaborative implementation model of an ICU telemedicine program that included over 6,000 unit stays from seven ICUs in a single academic medical center reported significant associations with improved outcomes. Implementation lowered hospital mortality from 13.6% to 11.8% with an odds ratio (OR) of 0.4 (95% CI, 0.31–0.52) and ICU mortality from 10.7% to 8.6% (OR = 0.37; 95% CI, 0.28–0.49). ICU LOS decreased from 6.4 to 4.5 days postintervention, consistent with increased quality and greater efficiency. Process-focused mechanistic analyses demonstrated that increased adherence to established critical care best practices and lower rates of complications were significantly associated with improved outcomes. Contrasting differences in care delivery process aspects with implementation of the ICU telemedicine program allowed identification of process changes that could account for lower mortality and LOS. Redundant processes for promoting ICU best practice adherence, less than 3 minute responses to alerts and alarms of physiologic instability, and initial care plan reviews by intensivists using dedicated workstations designed to track trends in physiologic parameters and laboratory values were identified as correlates of lower mortality and LOS.

The associations of these and other structural and process-based aspects of critical care delivery that were known to be impacted by some ICU telemedicine programs [93,94] were measured in a 2014 multicenter study [72]. This study analyzed 118,990 ICU stays among patients
admitted to ICUs between 2003 and 2008 across 56 ICUs in 32 hospitals from 19 US healthcare systems in a pre/postassessment of implementing an ICU telemedicine program. This study was notable for its size, statistical power, and scope as it was the first study to look at the effect of tele-ICU across the United States. Tele-ICU implementation resulted in improved outcomes, including a 20% lower ICU LOS (95% CI, 19%–22%; \( p < 0.001 \)) and lowering hospital LOS by 15% (95% CI, 14%–17%; \( p < 0.001 \)). More importantly, using a validated standardized survey [93] that reliably characterizes ICUs and their telemedicine structure and processes, additional analysis identified six individual quality improvement constructs that were drivers of larger improvements in mortality and LOS (Table 32.3). Many of these processes revolve around early proactive involvement by an intensivist, technology-enhanced alerting and reminding systems, or the use of data to drive quality improvement. Notably, the effects of individual process elements appeared to be small, but the cumulative effects were clinically significant and financially important [72]. This study is important because it identifies factors that explain some of the differences in outcomes among published studies. These factors involve how clinicians use telemedicine technologies, and it is increasingly clear that how the technology is used is at least as important as the technology itself.

**TABLE 32.3 Factors Associated with Improved Outcomes after ICU Telemedicine Implementation [72]**

- Workstation-assisted intensivist reviews of the care plan within 1 h of ICU admission
- Frequent and collaborative review and use of ICU performance data
- Near-perfect rates of adherence to ICU best practices
- Shorter response times for abnormal laboratory and alarms for physiologic instability
- Performance of interdisciplinary rounds
- High levels of perceived effectiveness of the institution’s ICU committee

ICU, intensive care unit.
In addition to the important patient-related outcomes revolving around ICU and hospital mortality, multiple investigators have evaluated the effect of tele-ICU implementation on several other relevant outcomes to understand its relevancy, usefulness, impact, and cost-effectiveness. In a consensus statement on the state of tele-ICU research [94], the Critical Care Societies Collaborative recommended the development of a comprehensive outcome evaluation including elements from the perspective of the patients, the providers, the healthcare system, and healthcare payers.

**Staff Perceptions and Satisfaction**

It is important to understand the bedside provider perspective as acceptance and buy in have been identified as hallmarks of effective programs [95]. Bedside provider enthusiasm depends on several factors, including how they were included in the change process and how long after program implementation their opinions were solicited. A survey administered in 2015 with respondents from a wide variety of hospitals related generally positive responses regarding all facets of tele-ICU [96]. In this survey, responders at hospitals with more frequent use and longer implementation periods were significantly ($p < 0.05$) more positive in their responses on multiple survey items than other respondents. Evaluation of ICU staff satisfaction and perceptions involving tele-ICU implementation has occurred among numerous smaller studies [97]. A recent systematic review including 23 studies involving staff acceptance indicated favorable perceptions by physicians and nurses across a variety of settings [51]. Despite initial skepticism, bedside staff believed tele-ICU improved the quality of care and would likely achieve its highest efficacy in healthcare settings with reduced resources. Staff acceptance is poorly characterized in peer-reviewed literature, but is increasingly important because of its vital role in operational success and critical care cost-effectiveness. Preimplementation inclusion in program planning, establishing the understanding and expectations of bedside staff, investigating the perceived need, and assessing the availability of local resources have been shown as factors that improve acceptance [98].

**Trainee Education**

Nearly half of the comprehensive tele-ICU programs include participation of residents and trainees for the care of critically ill patients [68]. Little is known regarding the effects of ICU telemedicine on the critical care educational experience. There has been an increased effort to detail the effects of telemedicine integration into medical education and critical care training programs [51,99]. These investigations suggest that the addition of an ICU telemedicine program provides more resources to
residents and fellows with documented educational support at times when their primary educator is not in the ICU [100]. Approximately 82% of residents surveyed responded that this technology improved patient care, 73% indicated that it enabled better care of their patients when they were on call, and 67% desired tele-ICU involvement in the care of their patients. The majority reported usefulness regarding ventilator management, supervision during arrests, blood gas interpretation, acute respiratory changes, and goal-directed therapy. Importantly, tele-ICU involvement was not perceived as having an overall negative impact on education and training.

Cost-Effectiveness and Reimbursement

The healthcare system’s viewpoint of tele-ICU programs is a unique perspective that is now being better defined because intense public scrutiny on higher-quality healthcare at lower costs has resulted in increased focus on cost-effectiveness. Currently, one must consider the cost-effectiveness of tele-ICU in the setting of a substantial initial capital investment [101] in technology along with increased operating costs on account of the general failure of payers to integrate models of tele-ICU payment into existing reimbursement systems [102]. Direct reimbursement for tele-ICU evaluation and management services is not supported in the United States at the time of publication of this text [103,104]. Payment for telehealth services does exist, but is limited through federal, state, and private insurance restrictions. Medicare and Medicaid public programs have paid for telemedicine services dating back to the federal Balanced Budget Act in 1997 when Medicare initiated formal payment models for telehealth services in rural areas [105]. However, Medicare spending on telemedicine remains a small fraction as only $5 million was allocated to telemedicine in 2012 Medicare spending which totaled $466 billion. To date, 47 states have some form of payment for telemedicine services through Medicaid, and 28 states have active laws governing private payer telemedicine coverage [106]. However, ICU telemedicine services are not among those that are eligible for reimbursement. Accordingly, one must consider the indirect financial aspects of a system’s ICU telemedicine program.

Until recently, the lack of transparent cost data along with the absence of a standardized methodology for assessing cost-effectiveness has limited the quality of literature surrounding the financial aspects of ICU telemedicine. In 2015, a comprehensive cost-effectiveness analyses of ICU telemedicine based on published literature suggested that ICU telemedicine was cost-effective when compared with ICU care without telemedicine [107]. Using simulation analyses, this study investigated the relationship of the cost of a tele-ICU intervention and its extension of
quality-adjusted life years estimating that ICU telemedicine was cost saving 37.2% of the time and cost-effective 66.8% of the time. This included a wide variety of sensitivity analyses using a broad range of assumptions. In 2013, a systematic review identified 8 studies from 29 ICUs that reported costs associated with tele-ICU implementations [101]. Wide variation in cost and reporting detail existed because the estimated cost of implementing the tele-ICU program, including the technology, monitoring, operations, and staffing for 1 year, ranged from $50,000 to $100,000 per ICU bed. The majority of these studies attempted to identify the impact of tele-ICU on hospital variable direct costs. Importantly, studies with a vendor connection reported a cost saving of $2,600 to $3,000 per patient and suggested that some tele-ICUs have increased hospital per case margin by $1,000 to $4,000 per patient [65,66,108]. Alternatively, studies without a vendor connection did not impact LOS and reported no variable cost savings and suggested increased hospital costs after implementation. It seems clear that the most frequently reported method for assessing cost savings is by gauging reductions in LOS. In community hospitals, positive financial outcomes have been reported because of increases in volume and acuity of critically ill patients who are retained as opposed to transferred elsewhere [108]. High-quality research involving the costs of tele-ICU programs remains limited and is one of the important barriers to growth.

Quality Metrics and Evidence-Based Care

Important data exist outside the hallmark outcomes of risk-adjusted mortality and LOS within a continuous comprehensive model of tele-ICU. There are an increasing number of focused investigations pertaining to the potential impact of ICU telemedicine on specific disease processes and quality performance improvements commonly encountered in the ICU. A responsive, or episodic, telemedicine care model has been shown to provide safe, reliable, cost-effective care that improves timely response to neurologic ICU emergencies, decreases hospital LOS, and improves functional outcomes [109–112]. The utility of neurology consultation using telemedicine tools to assess neurologic symptoms, review neuroradiologic imaging, determine the National Institutes of Health Stroke Scale score, and provide recommendations regarding the administration of tissue plasminogen activator for patients suffering a stroke is now broadly accepted [113,114]. Similarly, cardiology consultation utilizing telemedicine can potentially expedite the care of patients with ST elevation myocardial infarction or enhance the management for those with chronic congestive heart failure [115]. Prehospital triage and thrombolysis utilizing remote interaction with paramedics and ECG have been shown to decrease the time to
reperfusion in the setting of ST elevation myocardial infarction [116]. Additionally, telemedicine tools allowing home monitoring of patients with a diagnosis of congestive heart failure have been associated with a reduction in the rate of hospital admissions and an increase in quality of life [117]. The impact of telemedicine tools for both acute and chronic care delivery continues to evolve, and future investigations of the clinical and financial impact will help reduce the uncertainty for health system policy makers and payers.

Quality of healthcare has been defined by the Institute of Medicine as care that is safe, timely, effective, efficient, equitable, and patient centered [19]. Quality improvement involves activities that focus on process and outcome measures that often revolve around a particular disease entity or patient cohort [118]. There is an increasing belief that implementation of telemedicine in critical care delivery is uniquely capable of enhancing quality improvement programs by providing process-based metrics that are linked to outcomes [119]. Effective tele-ICU programs are well equipped to collect, assimilate, and analyze larger amounts of more granular data, invest dedicated human resources, and promote a culture of safety as the predominant force moving the program forward toward the desired result. Quality improvement programs often focus on “best practice” process measures such as adherence to the Surviving Sepsis Guidelines or procedures for the prevention of ventilator-associated pneumonia. Utilizing on-demand reports and smart alerts, telemedicine programs have increased compliance with early sepsis management protocols and ventilator bundle element [92,120]. In some instances, telemedicine integration for quality improvement has increased adherence to near 100% for preventative practices for pneumonia, stress ulcer prophylaxis, and deep vein thrombosis prophylaxis [121]. In 2014, the authors investigated the impact of tele-ICU–led ventilator rounds on protective lung ventilation compliance, ventilator duration ratio, and ICU mortality at multiple sites across 11 hospitals [122]. Despite wide variability in adherence rates to lung protective ventilation before the intervention across hospitals, there were statistically significant improvements in all measured outcomes. The effectiveness of telemedicine-directed ventilator rounds was attributed to the ability of the tele-ICU intervention to provide human support to encourage action based on data management and timely performance reporting [123].

Empirical research and clinical experience can provide a framework to optimize the effectiveness of ICU telemedicine. In 2014, guidelines were developed by the American Telemedicine Association (ATA) to assist critical care professionals in delivering safe, effective, and collaborative care through the tele-ICU, focusing on the unique aspects of utilizing audiovisual communications and computer systems for the delivery of
critical care services [124]. The ATA generated and reviewed 66 consensus guidelines to be used both as operational guidance and as an educational tool to aid in the appropriate care for critically ill patients in the ICU telemedicine model. Standards and recommendations included administrative, clinical, operational, and technical guidelines including aspects of leadership structure, patient privacy and confidentiality, documentation and storage, tele-ICU delivery and staffing models, licensing and credentialing, workflows, quality performance reporting, audiovisual and networking protocols, and data security. A comprehensive evidence database consisting of high-quality research derived through a sound methodological framework will be necessary to meet the standards of creating evidence-based guidelines for ICU telemedicine.
SUMMARY

As the changing critical care delivery paradigm becomes more apparent, the role of ICU telemedicine for meeting patient-centered and system goals for critical care is evolving. ICU telemedicine programs have improved access to critical care professionals, identified patients with evolving physiologic instability that has not been addressed, and helped to control costs associated with wide variation of care through standardization of care delivery processes. Widespread acceptance of telecommunications technologies has fostered the ability of telemedicine to make critical care professionals continuously available to geographically dispersed ICUs. These electronic systems enable remotely delivered comprehensive care, including the ability to independently evaluate patient care plans and deliver evaluation and management services. Although meta-analyses report improved quality outcomes, it remains evident that there is wide variation in the practice of ICU telemedicine programs. The substantial implementation and operational costs of ICU telemedicine programs are best justified by increased efficiency of critical care delivery. As enabling technologies become less expensive and better integrated with commercially available electronic health records, the incremental costs of telemedicine technologies are expected to decrease.

More research is needed on operational, quality, staffing, and financial outcomes from the point of view of all stakeholders, including patients, providers, hospitals, healthcare systems, and society as a whole. Divergent forces including an aging population growth, increased focus on controlling costs, and a maldistribution of ICU professionals have increased the need for adult critical care services and created interest in exploring the application of telecommunications technologies to improve the efficiency of critical care delivery. The ability to support the effective process of critical care delivery and to provide timely and actionable performance reports are key elements that promote high-quality ICU outcomes. ICU telemedicine interventions can leverage electronic tools to assist in ensuring that every patient receives appropriate intervention in the correct time frame in a reliable and cost-effective manner. The great promise of ICU telemedicine is its potential to improve outcomes yet control critical care costs.

PALLIATIVE CARE AND ETHICAL ISSUES IN THE CRITICAL CARE UNIT

JENNIFER E. REIDY
The integration of high-quality palliative care is an essential part of comprehensive critical care medicine. Critical care providers are often required to provide pain and symptom relief to patients with serious illness; conduct family meetings to clarify goals of care; give bad news; or deliver end-of-life care to terminally ill patients while providing support to their loved ones. It is important that critical care clinicians acquire basic palliative care skills for the management of pain and suffering and learn the necessary skills for effective serious illness conversations. The Institute of Medicine (IOM), now renamed The National Academy of Medicine, conducted a comprehensive evaluation of end-of-life care in the USA and found numerous shortcomings, concluding with a call to action for systematic improvement in access to high-quality palliative care across all care settings [1]. This is especially true for the intensive care unit (ICU), where death is common and those who survive their ICU stay often experience significant morbidity and emotional suffering months and even years post–hospital discharge [2]. In the USA, a significant portion of health-care expenditure goes toward the care of critically ill patients more than for any other country in the world [3], and a significant amount of this spending is for patients who die in the ICU despite the use of advanced technologies and therapeutic interventions. A recent national assessment of end-of-life care among Medicare beneficiaries found that 30% of beneficiaries have an ICU admission in the last month of life [4]. What is concerning is that the use of life sustaining therapies, particularly in the final days or weeks of life, may in fact not be consistent with actual patient preferences [5]. Another study found that 20% of all deaths in the USA occur in the ICU or shortly thereafter. In an effort to address the discordance between what patients
say they want and the care they actually get, the National Quality Forum developed a palliative care and hospice framework that advocates access for all eligible patients. This initiative also asserted that health-care providers in critical care require education and skills training in the practice of high-quality palliative care.

There are unique issues associated with providing palliative care in the ICU setting (see Table 33.1). Patients and families want both disease-modifying treatment and palliative care, and clinicians cannot always predict who will survive, who will die or who will remain chronically critically ill. For patients with terminal illness who are unlikely to benefit from life-sustaining treatments, an ICU admission can result in unnecessary suffering and treatment that may be discordant with their preferences for health care [6]. This often occurs from lack of prior conversations about patients’ goals and preferences for care as well as the appropriate available palliative options to meet those goals as an illness progresses over time. An ICU admission for a terminally ill patient can be associated with inadequate treatment of pain, anxiety, dyspnea, thirst and other symptoms. In addition, family members of critically ill patients can suffer significant psychologic distress such as anxiety; posttraumatic stress; and depression [6] which has been associated with low-quality communication and the high burden of medical decision-making [7]. Critical care clinicians experience the emotional labor of providing end-of-life care in an ICU setting, and can suffer moral distress and burnout.

Hospice and palliative medicine emerged as a distinct medical subspecialty in 2006 when it was recognized by the American Board of Medical Specialties. Palliative care is a team-based model of care that focuses on the relief of pain and symptoms related to serious illness,
regardless of prognosis. Palliative care teams include specially trained physicians, nurses, social workers, and chaplains who provide expert symptom management, clarify patients’ goals and values, and reduce the stress of serious illness for patients and their loved ones. Palliative care teams collaborate and coordinate care with a patient’s other clinicians while providing support to the patient and their family in the context of their lives, culture, faith, and community outside the hospital (see Table 33.2).

**TABLE 33.2 Expected Benefits from an Initiative to Improve ICU Palliative Care**

- Improved family satisfaction and comprehension
- Lower levels of family anxiety, depression, and posttraumatic stress disorder
- Less conflict in the ICU
- Timely implementation of care plans that are realistic, appropriate, and consistent with patients’ preferences
- Reductions in the use of nonbeneficial treatments and lengths of stay in ICU/hospital—with stable ICU mortality
- Professional gratification for clinicians
- Significant cost savings for the hospital

Ensuring access to high-quality palliative care across all settings from home to the ICU has become a national priority as patients and families begin to insist on better integration of goals and treatment plans. According to the National Palliative Care Registry, 90% of U.S. hospitals with more than 300 beds offered palliative care services in 2014 [8]. However, these inpatient teams were often understaffed and saw only 3.4% of annual hospital admissions on average. Based on national
demographics and hospital data, the Center to Advance Palliative Care estimates that at least 8% of all hospital admissions require specialty palliative care, which results in a gap of 1 to 1.8 million patients with unmet needs. The field of palliative medicine is facing a serious workforce shortage, with only 7,000 board-certified physicians in 2014 among 10 primary specialties, and the current capacity of fellowship programs remains insufficient to meet the need [9]. As a result, the field is focused on training all providers who care for people with serious illness in “generalist palliative care” skills (see Table 33.3) in addition to building subspecialty programs. The current transformation of health care from a fee-for-service to a shared-risk model also incentivizes health systems and payers to develop palliative care services, especially in caring for the sickest patients who are often high health-care utilizers. Multiple studies have shown that palliative care improves quality, and can reduce harm by avoiding unwanted, nonbeneficial, and costly admissions, procedures, and treatments at the end of life [10]. There are also small studies demonstrating palliative care can prolong survival in metastatic lung cancer, COPD, and among hospice patients [11,12].

There is often confusion about the difference between hospice and palliative care (see Table 33.4). Hospice is specialized palliative care during the final 6 months of life. Patients generally must also forgo most disease-directed therapies like chemotherapy and dialysis to be eligible for hospice care. Hospice care is generally provided where the patient lives (e.g., nursing home, home) but can also be provided in an inpatient setting for a variety of reasons including refractory symptoms and family respite care. Hospice care is a benefit covered by Medicare, Medicaid and most commercial health plans. In contrast, palliative care can be provided at any point during serious illness—even over many years—and is usually delivered alongside disease-directed treatments.

In an effort to promote best practices, the National Consensus Project Clinical Practice Guidelines for Quality Palliative Care created an important theoretical framework and practical guide to improve care [13]. The report promotes the philosophies embedded in palliative care and outlines essential elements to ensure quality, including the structure and processes of care; the physical, psychosocial, spiritual, and cultural aspects of clinical care; caring for the imminently dying patient; and ethical and legal aspects of care. Guided by these principles, palliative care has been shown to reduce physical and psychologic suffering [14]; increase patient and family satisfaction; and decrease ICU admissions,
ICU length of stay (LOS), and overall hospital costs [15]. This chapter discusses models for palliative care delivery in the ICU; clinical triggers for palliative care engagement; the barriers to palliative care; and quality improvement strategies.
EXPLORING MODELS OF PALLIATIVE CARE DELIVERY

An important feature of palliative care is that it can be offered simultaneously with medical treatments aimed at extending life, and does not require a distinct choice between treatment-focused critical care or comfort care. There are two approaches to palliative care delivery in the ICU: (1) the integrative model, which integrates palliative care practices into everyday critical care routines for all ICU patients; and (2) the consultative model, which relies on consultants to provide care for selected ICU patients [16]. Table 33.5 provides a synopsis of studies that have investigated different strategies and outcomes associated with both models. The consultative model has generally shown greater improvement of outcomes compared to the integrative model. Ideally, ICUs would implement a combination of both models and be capable of providing basic, generalist palliative care by ICU clinicians and referring more complex cases to the palliative care consultation team [17].

</tr>
</tbody>
</table>
Given the significant morbidity and mortality associated with critical illness, a large number of ICU patients and their family members will have palliative needs; therefore, integrating palliative care into the ICU routine and rounding protocols may be useful. Few ICU clinicians are fellowship-trained in palliative care, but formal training programs are becoming increasingly more common for clinicians at all stages of training. The Task Force from the Society of Critical Care Medicine, American College of Chest Physicians, American Thoracic Society, American Board of Internal Medicine, and the Association of Pulmonary and Critical Care Medicine Program Directors recommend palliative care training for ICU clinicians [18]. Based on this overwhelming consensus, educational efforts should be targeted for physicians, nurses, social workers, chaplains, and other members of the critical care team to strengthen the internal capacities for integrated ICU palliative care.

**Integrative Models**

Strategies to integrate palliative care into ICU practice have demonstrated variable results. A single center study showed significant improvement for nurse-assessed quality of dying and reduction of ICU LOS [19], but the same group assessed these outcomes in a multicenter study and found no improvement [20]. This suggests that it may be useful to focus on a narrow range of clearly defined goals that are achievable in individualized settings and culture given the locally available resources. One such example is the “care and communication bundle [21]” that addresses domains of palliative care quality that have been identified as important by ICU patients, families and professionals. Based on this bundle, there are preset ICU LOS triggers to identify medical decision-makers; investigate advance directives; address preferences for resuscitation; distribute information leaflets; offer social work and spiritual support; and conduct interdisciplinary family meetings. Pilot testing of this bundle in 19 ICUs showed feasibility and also revealed opportunities for improvement in clinician–patient–family serious illness communication [22]. A recent systematic review of factors associated with family satisfaction with end-of-life care in the ICU found
recurring themes of higher satisfaction with good quality communication and expression of empathy by physicians, supporting the value of communication bundles [23].

An area of ICU practice for which evidence of palliative care integration is emerging is during rapid response team activations. An initial study by Jones et al. found that issues surrounding end-of-life care and limitations of medical therapy arose among approximately one-third of rapid response calls, suggesting an area for further integration [24]. A retrospective chart review at a Veterans Administration hospital in New York evaluated rapid response calls and found a 28% incidence of do not resuscitate (DNR) order placement after the call, suggesting that rapid response teams must frequently have an emergent goals-of-care conversation during a crisis [25]. Another study from Canada found that rapid response calls led to an increased incidence of patient and family conferences regarding treatment preferences within 48 hours [26]. This highlights the need for palliative care clinicians and other members of the rapid response team to be well skilled in having conversations about preferences for end-of-life care, particularly during a hospital admission or at times of hemodynamic instability. Strategies include clinician training for complex goals-of-care discussions and system initiatives to enhance awareness of opportunities to initiate goal-oriented conversations and avoid burdensome or unwanted ICU care (see Chapter 34).

Consultative Models

The consultative model for the ICU focuses on increasing the involvement and effectiveness of palliative care consultants for the care of ICU patients and their families, especially those at highest risk for poor outcomes. Typically, the consultative model can only accommodate a subset of the most challenging or symptomatic patients rather than all patients in the ICU, owing to the workforce shortage of palliative care providers and lack of round-the-clock, on-site coverage. The consultative model has helped to identify proactive clinical triggers for palliative care consultation. One study used five clinical triggers for automatic consultation: pre-ICU admission hospital LOS >10 days; age >80 years; terminal malignancy; status post–cardiac arrest; and intracerebral bleed requiring mechanical ventilation [27]. Other studies have used advanced dementia; multiorgan dysfunction syndrome; and the prior requirement for CPR as useful clinical triggers.
Consult teams may generate a halo effect resulting from their increased presence in the ICU, indirectly influencing care of other patients through modeling high-quality serious illness communication and symptom management. This may be especially true for conducting complex family meetings. Other providers may attend a specialist-led family meeting to discuss serious illness, observe skilled palliative care clinicians, and in turn apply some of the communication strategies to their own practices. An important advantage of the consultative model includes expert opinion from an interdisciplinary team of specially trained palliative care physicians, nurses, social workers, and others who can offer continuity of care before, during, and after an ICU admission, including transfer out of the ICU for end-of-life care when needed.

As a practical matter, many ICUs will function best with a hybrid model that offers the advantages of both the integrative and consultative models. A systematic review evaluated interventions in the ICU that improved end-of-life care and found that high-quality communication was the single most important factor for improving care, irrespective of the model [28]. Communication initiated by the palliative care consultants, along with family meetings and psychosocial support, improved quality in end-of-life care and family satisfaction. For the integrative model, trainees and interdisciplinary staff in an ICU showed higher rates of end-of-life discussions. Like any ICU procedure, conducting an effective family meeting requires training, skills practice, and feedback. The best model for any specific ICU depends on the locally available resources, particularly related to education, training, and commitment from all ICU clinicians to strengthen their knowledge and skills for palliative care practice. In addition, receptivity for collaboration with a multidisciplinary team is the key to efficient delivery of palliative care irrespective of the model.
TRIGGERING PALLIATIVE CARE IN THE ICU

Patients who are likely to benefit from palliative care consultative services should be identified early in their ICU stay. However, recognizing this population and initiating appropriate palliative care interventions are often at the discretion of the treating physician, potentially limiting the impact of consult teams. Over the last decade, a number of studies have investigated the use of standardized triggers to proactively initiate a palliative care consultation (Table 33.6). One medical ICU study proposed clinical parameters such as age greater than 80 years; LOS >10 days; prior cardiac arrest; terminal malignancy; and intracerebral bleed requiring mechanical ventilation as triggers initiating palliative care consultation and found that patients in the proactive palliative care group had significantly shorter ICU LOS [27]. Another study that used advanced dementia as a trigger to offer early assistance to the ICU staff found a decrease in hospital and medical ICU LOS. Notably, a proactive approach to palliative care intervention decreased the time between identification of the poor prognosis and the establishment of a DNR order and also reduced the use of nonbeneficial resources, which resulted in reduced patient and family burden and lower cost of care. In the severe brain injury cohort, the trigger-based approaches resulted in earlier and more systematic discussions with families about prognosis, patient values, and acceptable quality-of-life outcomes. In addition, there were higher rates of family satisfaction and a decrease in the number of tracheostomies for chronic respiratory failure [29].

• Disagreement regarding treatments among stakeholders (clinicians, patient, family members)
• Quality-of-life concerns
  Surgical ICU triggers
• Greater than three admissions to the SICU during the index hospitalization
• Length of surgical ICU stay >1 month
• Multiorgan failure >3 organ systems in a patient over 60 years of age
• Transcranial gunshot wound
• Any disease with median survival < 4 months
• Family request
• GCS <8 for >1 week
• Carcinomatosis and unresectable malignancy

ICU, intensive care unit; SICU, surgical intensive care unit; GCS, Glasgow Coma Scale.

Others have used prognostic triggers such as patients with a terminal condition as determined by the physician or a high risk of hospital death despite the continuation or escalation of medical therapies [30]. Patients with advanced cancer experience a complex web of these problems and evidence has demonstrated that specialist palliative care significantly improves patient outcomes in the domains of pain, symptom control, anxiety, and also reduces hospital admissions. In addition, patients with a palliative care consultation have higher rates of DNR orders before death suggesting they are protected more often from nonbeneficial cardiopulmonary resuscitation [31]. Evidence shows that families of patients who have a palliative care consultation during the last month of life are more satisfied with goals-of-care discussions and staff communication prior to their loved one’s death [32].
The use of proactive clinical triggers for palliative care has demonstrated favorable outcomes in many settings. In the outpatient setting, patients are significantly more likely to have discussions about goals of care, improved quality of life (QOL) and lower depressive symptoms with trigger-initiated palliative care consultation. Specific to critical care, several studies showed that proactive approaches to palliative care consultation improve the concordance between the care provided and the care the patient actually wanted; increased use of advance directives; increased hospice referrals, and less use of nonbeneficial life-prolonging treatments for patients who are dying. A proactive palliative care approach has demonstrated a decreased ICU LOS; decreased hospital LOS; and less aggressive ICU interventions for patients that die in the ICU. Proactive palliative care has also shown to improve family satisfaction with the quality of care; understanding treatment options; and bereavement outcomes. Several outpatient studies have demonstrated that patients with serious illness who receive palliative care live longer, and proactive palliative care consultation has shown no increased mortality or discharge disposition [27].

One study looked at objective physiologic and medical parameters to predict palliative care need without consideration of communication or psychosocial factors. This study showed that about one in seven ICU patients could benefit from palliative care. There was no significant variation between the type of hospital (community vs. academic) or type of ICU (surgical, medical, neurologic, and mixed), and the prevalence of patients meeting certain palliative care triggers. Thus, the authors concluded that approximately one in seven ICU admissions met triggers for palliative care consultation using a single set of triggers, with an upper estimate of one in five patients using multiple sets of triggers. Notably, the triggers investigated by the authors were all objective, and clinical criteria and did not include issues such as ethical dilemmas, communication challenges, or symptom management; therefore, this is probably an underestimation of the number of ICU patients who would benefit from palliative care consultation [33]. Because palliative care needs are not unique to medical ICUs, various professional societies have their own specific guidelines. The American College of Surgeons convened a consensus panel of surgical palliative care specialists and surgical intensivists and developed “ten trigger” criteria for palliative care consultation, including multiorgan failure; expectation of death in the SICU; length of SICU stay >1 month; and more than three admissions to the SICU during the index hospitalization [34]. Several of these clinical criteria directly addressed terminal conditions, whereas others associated with a poor prognosis for neurologic recovery were also included (such as a Glasgow Coma Scale score <8 for more than 1 week in a patient older than 75 years). Triggers in the surgical literature can be used to
proactively and systematically improve palliative care access for patients and families.

From the oncology literature, a concept known as “early palliative care” or “early integration” has been recommended by organizations such as the American Society of Clinical Oncology. The recommendation is that palliative care should be provided in all stages of advanced cancer in conjunction with disease-modifying treatments and is supported by randomized-controlled trials [35]. A recent study has also demonstrated that cancer patients receiving palliative care spend less time in the hospital or ICU; and have a better QOL, less depression, and longer survival [11]. Similarly, the American Thoracic Society instituted the End-of-Life Care Task Force whose primary purpose was to identify the core values and principles related to palliative care. Among the recommendations is that palliative care services be provided to all patients with chronic or advanced respiratory disease, regardless of age or social circumstances.
RECOGNIZING AND ADDRESSING BARRIERS TO PALLIATIVE CARE IN THE ICU

There are several important barriers to reliable high-quality palliative care delivery in the ICU, including educational gaps; time constraints; and local cultures of ICUs.

Physicians practice how they were trained. Most physicians practicing today did not receive formal training in communication; pain management; or spiritual assessment regarding the impact of serious illness on patients and their loved ones. Because all physicians received extensive training and supervision in the diagnosis and management of disease, it is often the default to offer and provide more medical treatments to patients regardless of their values and preferences, which often go unknown. Providers may lack the essential core skills to conduct an effective family meeting aimed at discussing serious illness; treatment options including palliative care; and patient or family preferences. Great efforts over the past few years to correct these knowledge and skill deficits are underway [36]. For example, an evidence-based conversation guide for providers regarding serious illness is available as a checklist to facilitate these difficult communication tasks [37]. The purpose of this script is to provide a framework for the clinician with phrases to use during a conversation about treatment preferences in the context of serious illness. This tool includes scripted sentences such as “What are you worried about most right now?” There are well-placed pauses intended to help the clinician be quiet and listen to the patient and family member, which allows them to process strong emotions; absorb medical information; and engage in important decisions. Such a tool models best practices and prompts clinicians to use, for example, periods of silence to more effectively listen and discern goals and values in order to make an appropriate treatment recommendation (e.g., to continue or discontinue the ventilator).

Knowledge gaps exist regarding pain and symptom assessment as well. Pain, dyspnea, and thirst are three of the most prevalent, intense, and distressing symptoms in ICU patients, but often underrecognized and undertreated. An interdisciplinary advisory board of the Improving
Palliative Care in the ICU (IPAL-ICU) Project conducted a comprehensive review of literature in 2014 on the palliation of pain, dyspnea, and thirst. They identified evidence-based approaches for assessment and treatment, and recommended training of clinicians and well-designed work systems to implement best practices to ensure comfort and improve outcomes for the critically ill [38]. Pain management and palliative care are increasingly part of the core curricula in medical and nursing schools, and incorporated into academic milestones within residency and fellowship programs. A working group from the American College of Chest Physicians, the American Thoracic Society, the Association of Pulmonary and Critical Care Medicine Program Directors, and the Society for Critical Care Medicine designed entrustable professional activities that require pulmonary and critical care fellows to master the skills in facilitating effective family meetings and providing palliative care to patients and their families [39].

Another challenge is the fast pace and acuity of ICU care, which requires management of symptom crises and urgent decision-making about life-sustaining therapies without prior knowledge of patient preferences. This time pressure creates unique and additional stress on families and ICU staff. National leaders in critical care and palliative care have developed curricula for teaching and practicing urgent goals of care discussions during a medical crisis (see Table 33.7). In addition, the adoption of regular, brief family meetings from the beginning of an ICU stay about a patient’s medical status, prognosis, and goals (before a new crisis) has been shown to reduce anxiety, depression, and posttraumatic stress in family members, as well as reduce nonbeneficial health-care utilization as a side effect [40]. As a further incentive, it is important these conversations are billed appropriately to compensate providers for this high-level work. In the USA, reimbursement for critical care professional services is time-based, and current Center for Medicare and Medicaid Services (CMS) guidelines allow physicians to include time spent communicating with family members when the following criteria are met: (1) the patient does not have decision-making capacity and cannot participate in the meeting; (2) the clinician is on the floor or unit while communicating with families (by telephone or in person); and (3) the discussion focuses on patient management and medical decision-making. More recently, CMS announced that they will reimburse “advance care planning” conversations in both inpatient and outpatient settings as of January 2015, and these discussions should be documented and billed separately, much like technical procedures.

Finally, assessment of local ICU culture is crucial for understanding potential barriers as well as opportunities of palliative care growth. Some ICUs embrace family meetings, include family members during rounds and encourage 24/7 visitation, whereas other ICUs are less forward facing to family members. As more data emerges regarding the negative impact of an ICU death on survivors, a trend is emerging toward family-centered ICU structures. The American College of Critical Care Medicine created evidence-based clinical practice guidelines for support of the family in the ICU [38] (see Table 33.8). Evidence and models from pediatric and neonatal ICUs suggest increased family satisfaction when loved ones are included in daily rounds, but highlight the need for careful design to maintain efficient workflows; patient privacy; and integration of teaching students, residents, and fellows. Some medical ICUs have
incorporated “Get to Know Me” posters that encourage family to share personal information and photographs. ICUs that foster partnership with families and collaboration within their interdisciplinary teams may be better equipped to prevent or manage conflict, and help families and staff alike to cope with suffering. Much like central line infections, dying badly or in a manner discordant with patient preferences should become a “never event” within ICU culture.

1. Medical ICUs have increasingly adopted a closed model of care in which the intensivist is the primary provider; however, surgical ICUs often utilize an open model in which the surgeon retains primary care responsibility throughout the critical illness. Surgeons may have been trained to cure, and focus on mortality endpoints rather than patient-oriented endpoints. Death may be seen as a personal failure rather than the natural course of a terminal disease, which can lead to avoidance or poor communication with family about prognosis and end of life care. The surgical perspective is discussed in Chapter 55. In many of these ICUs, surgical intensivists may have less influence in discussing goals of care and shared decision-making. The Improving Palliative Care in the Intensive Care Unit (IPAL-ICU) [41] group recommended addressing attitudes and culture change through local champions and grassroots quality engagement to improve palliative care for the surgical and trauma professionals.

### TABLE 33.8 Selected Recommendations from the American College of Critical Care Medicine Clinical Practice Guidelines for Support of the Family in the Patient-Centered Intensive Care Unit [38]

- Practitioners fully disclose the patient’s current status and prognosis to designated surrogates and clearly explain all reasonable management options.
- ICU caregivers strive to understand the level of life-sustaining therapies desired by patients, either directly from those patients or via their surrogates.
- Family meetings with the multiprofessional team begin within 24–48 hours after ICU admission and are repeated as dictated by the condition of the patient with input from all pertinent members of the multiprofessional team.
• Nurses and physicians assigned to each patient are as consistent as possible.
• Families are encouraged to provide as much care as the patient’s condition will allow and they are comfortable providing.
• Family support is provided by the interprofessional team, including social workers, clergy, nursing, medicine, and parent support groups.
• The inter-professional team is kept informed of treatment goals so messages given to the family are consistent, thereby reducing friction within the team and between the team and family.
• A mechanism is created whereby all staff members may request a debriefing to voice concerns with the treatment plan; to decompress; to vent feelings; or to grieve.
• Spiritual needs of the patient are assessed by the healthcare team, and findings that affect health and healing are incorporated into the plan of care.
• Physicians review reports of ancillary team members such as chaplains, social workers, and nurses to integrate their perspectives into patient care.
• Open visitation in the adult intensive care environment allows flexibility for patients and families, and is determined on a case-by-case basis.
• Whenever possible, adult patients or surrogate decision-makers are given the opportunity to participate in rounds.
• The family is educated about the signs and symptoms of approaching death in a developmentally and culturally appropriate manner.
• As appropriate, the family is informed about and offered referral to hospice, palliative care, or other community-based health-care resources.

ICU, intensive care unit.
Quality improvement measures and related initiatives have swept through medical care at a rapid pace, especially with health-care reform. Landmark reports have demonstrated unacceptably high rates of medical errors and hospital-acquired complications, in addition to mandates around transparency and financial penalties for poor performance. Inevitably, the lack of palliative and end-of-life care has emerged as a major quality improvement issue, and this is particularly germane for ICUs owing to the morbidity and mortality associated with critical illness. Additionally, health systems are now being “graded” on their hospital mortality ratios as well as measures of patient–physician communication and patient/family satisfaction, and palliative care can often impact these scores.

A useful lens for viewing palliative care as a quality improvement topic is the commonly applied Donabedian framework in which health-care quality outcomes are contingent upon the structures and processes of care within a health-care delivery system. The structure of palliative care services includes triggers; clinical models of care delivery; availability of palliative care expertise; and symptom management protocols. Examples of process measures include routine, structured family meetings; obtaining and documenting treatment preferences; and assessing and managing symptoms. Clinical outcomes such as mortality should be balanced with patient- and family-centered outcomes such as the QOL; quality of dying; decision-making processes at the end-of-life; and bereavement. Embedded in these clinical outcomes are issues of symptom management; communication; and adherence to patient goals and values. Other important quality outcomes include utilization of ICU resources and cost savings from nonbeneficial and unwanted care at end of life [5]. Ensuring that patients get the care they want and value may be the most powerful metric; however, this remains difficult to measure.

The National Quality Forum and the “Measuring What Matters” campaign [42] have studied and endorsed a variety of quality measures for palliative care. These measures could readily be applied to specific ICU-based quality improvement initiatives, such as improving pain control in the final 48 hours of life; assessing and treating dyspnea quickly; screening for spiritual distress; and triggering family conferences. Given the challenges intrinsic to outcome measures in
palliative care, several consensus panels recommend indicators of structures and processes of care as proxies to reflect the quality of palliative care in the ICU. Process of care quality indicators for ICU palliative care include routine, structured family meetings; determining treatment preferences and surrogate decision-making roles; symptom management; and psychosocial support during and after end-of-life care. Quality indicators with respect to organizational structure include availability of palliative care consultative teams, religious/spiritual support services, protocols for withdrawing or withholding life support, and family-centered, open visitation spaces and policies.

An example of systematic palliative care integration through performance improvement is the “care and communication bundle,” which was developed as part of the national Transformation of the ICU program by the Voluntary Hospital Association (VHA), Inc. This bundle of measures evaluates nine evidence-based care processes in established quality domains, using a denominator of patients in the ICU for at least 5 days (see Table 33.9). The program uses a time-triggered strategy to prompt critical palliative care processes by scheduling them into specific ICU days. On Day 1 of admission, the team identifies a medical decision-maker for a patient, followed by a serious illness conversation with documentation of advance directives and resuscitation status. On Days 2 through 5, there are daily family meetings to discuss ongoing goals of care or acute events. The program also included providing an informational brochure that introduced families to the ICU; the roles of each health-care providers, and logistics such as phone numbers and parking information. Before or by Day 3, patients and families were referred to social workers and/or chaplains for emotional, psychologic, and spiritual support as needed. Each day, the program required routine pain assessment, treatment and follow-up to ensure optimal care. The VHA “care and communication bundle” is posted on the National Quality Measures Clearinghouse website and maintained by the Agency for Healthcare Research and Quality [43]. The bundle formed the basis of a large-scale collaborative improvement project by multiple ICUs in the VHA TICU program, a major faith-based hospital system, and medical ICUs in the Veterans Integrated Service Network.

Other quality measures under scrutiny are hospital mortality rates, which are now publicly reported. The value and meaning of these ratings are debatable [44]. Some mortality rates are global and apply to an entire hospital or organization, whereas others are specific to an illness such as pneumonia or myocardial infarction. Within this reporting, it is important to delineate hospital deaths that are expected or unavoidable, especially when dying patients are admitted for terminal care. The reporting entities that construct mortality rates have grappled with this issue, using various strategies with proprietary statistical tools [45]. In order to better understand how palliative and hospice care codes impact hospital mortality rates, one study compared methodologies between four major vendors and found substantial variation [46]. Certain palliative care codes impact the inclusion or exclusion of decedents for some reporting entities and make this data difficult to compare in a meaningful way. As a result, some patients who receive end-of-life care in a hospital setting may indeed impact hospital-specific mortality data. The variations present among hospital mortality rate determinations in general and specifically with respect to palliative care offer a cautionary note, and ICU clinicians’ efforts are probably best spent at this time on substantive strategies and assessment tools to improve the quality of bedside care for palliation in the ICU.
A new approach to better meeting the palliative needs of ICU patients begins with an organized initiative, including a working group, a needs assessment, and a focused action plan. A working group should include critical care clinicians (including the ICU medical and nursing directors), palliative care experts, nurses, social workers, chaplains, case managers, pharmacists, and administrators who demonstrate commitment and can serve as local champions and sponsors. Although palliative care has empirically demonstrated benefits, it is important for these stakeholders to adapt these lessons to their local ICU culture and resources. Initial planning should be based on a survey of existing clinical, educational, and financial resources to enhance feasibility and success without overwhelming the system. The working group should conduct a needs assessment to define problems; identify opportunities for improvement; and prioritize their agenda. This process also helps build support within the ICU and provides baseline data for evaluating results, which can be leveraged to strengthen a case for more resources from hospital leadership. Potential sources of data include patient mortality; LOS; readmissions; patient symptom ratings; family satisfaction surveys; presence of documentation of surrogate decision-makers in the medical record; proportion of patients seen by specialty palliative care; and surveys or focus groups of ICU staff.

Based on the needs assessment and inventory of resources, the working group should identify a specific and actionable opportunity for improvement relevant to their specific ICU. Examples include improving patients’ symptoms through the regular use of assessment scales and analgesic equivalency charts, or improving communication with patients and families with structured family meetings (see Table 33.10).

**TABLE 33.10 Example of an Abbreviated Action Plan**
Some of the most important aspects of successful integration of palliative care in the ICU include cultivating key stakeholders; designing effective and efficient systems for delivering palliative care; and promoting institutional culture change. The interdisciplinary leadership
is crucial in elevating the importance of psychosocial, spiritual, and cultural factors that contextualize people’s suffering and inform decision-making by patients and families [47].

Education and training of clinicians, as described above, is critical to early success but also long-term sustainability of integrated palliative care. Clinicians must learn to manage multiple symptoms in patients with multiorgan failure and potential adverse effects from medications. They also should understand the legal and bioethical constructs for surrogate decision-making and limits on life-prolonging therapies, as well as strategies for dealing with uncertainty about prognosis and conflict resolution. This education should include skills practice, especially in advanced communication procedures such as sharing prognosis and discussing goals of care. These communication procedures can be especially challenging owing to the acuity of illness; incapacitated patients; reliance on surrogate decision-makers; and the lack of longitudinal relationships with patients and families. Whereas physicians provide information on diagnosis and prognosis, families provide expertise on patients’ beliefs and values. The recommended framework is a shared decision-making model in which the physician and family jointly assume responsibility for decisions about end-of-life care.

In order for evidence-based education and training to translate into everyday clinical practice, structural and process factors that facilitate high-quality palliative care in the ICU are essential. These include the availability of specialists and multidisciplinary care teams, the feasibility of the consultative versus integrative models, and the creation and implementation of protocols. The protocols and order sets should address routine pain and symptom management; documentation of advanced directives; time-triggered family conferences; withdrawal of life support; and discharge for survivors to community-based palliative care or hospice.

Effective implementation of any program involves setting short- and long-term goals, and varies depending on the need of each ICU. For example, a working group might begin with a specific plan to improve communication between ICU clinicians and families (organizing regular family meetings; designing a meeting guide; and involving nurses in family meetings) that evolves into broader system changes over time (creating templated, retrievable electronic notes about goals and care preferences; hiring and incorporating chaplains, redesigning patient rooms and hospital spaces for more comfortable and effective family meetings.). Once integration of palliative care into the ICU environment
is successful, focus should be directed to sustain it by creating a supportive ICU environment such that members of the interdisciplinary team feel responsible, empowered, and respected. This can be done by regular team huddles or debriefs that address ongoing challenges and quality concerns.

Nearly one in five Americans die during a hospitalization that involves ICU care, and nearly 100,000 ICU survivors continue with critical illness on a chronic basis [6]. Critical care providers play a key role for ensuring that high-quality palliative care is reliable and available to all patients with advanced illness in the ICU and their loved ones. This requires a commitment to ongoing palliative care education with training and feedback; regular assessment of quality measures such as symptom scores and numbers of structured family meetings; and measurement that care provided was concordant with patient preferences. This last measure, perhaps the most difficult to measure, is especially important as we strive to deliver the type of critical care that people want and value. The successful integration of palliative care is an essential to the delivery of high-quality critical care, especially the effective management of pain and symptoms of advanced illness and the mastery of skills required for serious illness communication.

REFERENCES

Timely, clear and compassionate communication is crucial to the care of critically ill patients and their families. Intensivists regularly share complex medical information, navigate prognosis and goals of care (GOC), and lead emotionally charged meetings with patients and families as part of their daily work. However, few clinicians receive formal training in communication skills and ethical decision-making. The costs of poor communication can result in increased patient and family psychological trauma, increased conflict, delayed or ineffective medical decision-making, moral distress among the ICU team, and the use of potentially inappropriate ICU resources. This chapter explores an approach to effective communication in the ICU, and the bioethical frameworks that guide shared decision-making between patients, families and clinicians.

FAMILY MEETINGS AND GOC DISCUSSIONS

Structured Family Meetings to Improve Communication

Communication presents one of the greatest challenges and therapeutic opportunities for medical care, regardless of clinical setting. Common barriers to communication include poor clinician training, time
pressures, medical or legal concerns, and chasms of culture and health literacy [1,2]. Serious illness has potential to raise spiritual, existential, emotional, social, financial, and functional concerns for both the patient and his/her loved ones [3,4]. Patients and families meet numerous subspecialist physicians, specialized nurses and technicians and, in academic centers, trainees of every level, while patient care needs may change by the hour. Fragmented communication can create suffering and safety concerns, reducing satisfaction with care and increasing risk of malpractice claims [5–7].

The “family meeting” has been identified as a strategy to prevent miscommunication and directly address the emotional distress caused by the intensive care environment [8–10]. The term “family” will be used in this text to refer to a patient’s loved ones, patient’s legal guardian, health proxy, caregiver, next of kin, civil partner, clergy or friends that the patient has empowered to participate in his or her care. Such meetings save time and confusion by allowing a patient’s loved ones to express feelings, hear each other’s concerns, and ensure that the patient’s individual goals and values are understood. This point has been evidenced by studies showing that an interdisciplinary communication intervention resulted in earlier consensus around goals and reduced length of stay in trauma ICU and liver transplant patients, without an increase of mortality [11,12].

Practitioners can promote quality care by using a consistent, evidence-based approach, planning ahead, and through skillful collaboration with the care team (Table 34.1). General discussion of clinical status, prognosis, patient-centered goals and options should be initiated by intensivists and the outpatient providers who have patient-valued relationships, such as oncologists, cardiologists and primary care clinicians. Such communication is considered to be “generalist” palliative care provided by many health professionals, while the expertise of the palliative care consultant is reserved for issues that remain unresolved in spite of the efforts of primary clinicians [13].

</tbody>
</table>
- Provide prognostic data using a range
- Respond to emotion

Although I can’t give you an exact time, given your illness and condition, I believe you have (hours to days) (weeks to months). This is an average, some live longer and some live shorter.

### 7. Assess Patient/Family Goals

**Possible Goals:**
- Prolong life
- Improve function
- Return home
- See a family milestone
- Relief of suffering
- Staying in control

- What do you wish to accomplish?
- Are there any important goals or tasks left undone?
- What is most important to you at this time?
- Knowing that time is short, what goals do you have?
- How do you picture your death?
- Where do you want to be when you die?

### 8. Present Broad Care Options

- Stress priority of comfort, no matter the goal
- Make a recommendation based on knowledge/experience

Given what you have told me about your mother and her goals, I would recommend…

These decisions are very hard; if (patients name) were sitting with us today, what do you think he/she would say?

How will the decision affect you and other family members?

### 9. Translate Goals into Care Plan

- Review current and planned interventions—make recommendations to continue or stop based on goals
- Discuss DNR, hospice/home care, artificial nutrition/hydration, future hospitalizations
- Summarize all decisions made
- Confirm your continued availability regardless of decisions

You have told me your goals are ______. With this in mind, I do not recommend the use of artificial or heroic means to prolong your dying process. If you agree with this, I will write an order in the chart that when you die, no attempt to resuscitate you will be made, is this acceptable (ok)?

All dying patients lose their interest in eating in the days to weeks leading up to death; this is the body’s signal that death is coming.

I am recommending that the (tube feedings, IVF) be discontinued (or not started) as these will not improve her living and may only prolong her dying.
10. Document and Discuss
- Write a note: who was present, what decisions were made, follow-up plan
- Discuss with team members (consultants, nurse, etc.)
- Check your emotions

Team Debriefing = Opportunity for Teaching and Reflection
Ask team members:
“How do you think the meeting went?” “What went well?” What could have gone more smoothly? “What will you do differently in the future?”

Managing Conflict

➤ Listen and make empathic statements
➤ Determine source of conflict: guilt, grief, culture, family, dysfunction, trust in med team, etc.
➤ Clarify misconceptions
➤ Explore values behind decisions
➤ Set time-limited goals with specific benchmarks (e.g., improved cognition, oxygenation, mobility)
➤ When you need additional assistance or support, consider a palliative care consult.

Adapted from Weissman DE “The Family Goal Setting Conference” and “Communication Phrases Near the End of Life” pocket cards from Medical College of Wisconsin.

Interventions such as rounding tools and triggers have been used to ensure consistent communication practices. Triggers (see Chapter on Integrating Palliative Care in the ICU), including clinical factors, number of days in ICU, and staff assessments, can be used to prompt a structured family meeting with the ICU team and/or a referral to palliative care. Such triggers may be tailored to institutional goals, needs of a specific unit or patient population, and availability of ICU practitioners and palliative specialists. Structured approaches to communication are recommended to improve quality and timing of this important intervention [14] with extensive evidence for use in the ICU setting [15].

Evidenced-based curricula on communication training skills have been shown to be feasible and effective for clinicians [16]. The Vital Talk program [17] and the Critical Care Communication (C3) Course for intensive care fellows are high-quality examples. Such courses address knowledge, skills, and attitudes regarding serious illness communication. Because clear communication is so commonly needed following a resuscitation event, authors have also evaluated the need for skills in discussing bad news or goals of care linked with resuscitation exercises, which elicit a spectrum of emotional reactions within the clinician [18,19]. Clinicians can also “practice” by using skills in simpler, less
emotionally charged interactions—ideally with feedback from mentors and inter-professional peers.

ICU-based initiatives and systematic literature reviews have identified key concepts in approaching family meetings, from vital preparatory steps to coherent documentation [8,20,21].

Anticipation: What to Discuss and Why

Determining the goal and content of the meeting sets the tone and guides subsequent steps. Failing to identify a shared goal can lead to confusion for the family and conflict for the care team. Through careful chart review, discussion with clinicians, and sharing one’s intention with the patient or his/her proxy, one can refine the goals and create a shared agenda. Consensus about diagnosis, prognosis and treatment options should be reached during pre-meeting preparation. Patient/family distress will escalate if they perceive that physicians disagree or are not communicating effectively. The input of multiple specialists, (either in person, speaker phone or via relayed conversations) is helpful in situations where such information is vital for decision-making or for patient/family understanding.

When appropriate, advanced care planning documents are reviewed prior to the meeting for verification of patient proxy (for incapacitated patients) and values (if related to the clinical scenario). Discussions with outpatient physicians, social workers, nursing and spiritual care providers can reveal psychosocial and cultural influences on prognosis, treatment options and communication. Tensions among family members or between family and staff should be noted, but should not bias the perspective of the practitioner.

Anticipation: Whom to Include in the Family Meeting

After determining the goal of the meeting, consideration should be given to how the patient is represented. If doubt exists about patient capacity, an assessment should be performed (see section later in this chapter on “determining decision-making capacity”), as patients with the waxing and waning sensorium may lose or regain capacity quickly. Patients with dementia may also “cover” by giving vague answers and responding to social cues without real understanding. In general, encouraging a health care agent to attend the meeting is always advisable, especially if the patient has variable capacity or memory impairment, but also to prime the health care agent for future decision-making if and when the patient
loses capacity. Patients vary with regard to their desires to participate in decision making [22]. When explaining the goal of the discussion, inquire whether the patient prefers to be fully involved or if emotions or culture prompt him/her to defer. While a patient may be culturally expected to defer decision making, the patient should be asked what role her or she would like to play.

If the family request withholding information from the patient, understand the reason for the request. Common fears are often allayed with careful explanation and reassurance. Studies indicate that patients do not become more depressed when given a serious diagnosis [23]. Discussing the risks of non-disclosure—i.e., that the patient may already fear the worst, may make bad choices due to misinformation, or will eventually learn of the deception with devastating results—is important, as is explaining that disclosure will occur compassionately and only with patient consent to receive this information [23]. For a supportive presence, patients or surrogates may identify family, friends, or clergy. Many families have complex structure; it is helpful to ask open-ended questions to identify the necessary participants. Telephonic (including video) participation of those who cannot be present saves time and confusion. Encouraging the patient or surrogate to have a “second set of ears” (family member, friend, or staff member) can alleviate anxiety.

An interdisciplinary approach to the meeting will best meet the multifaceted needs of patients and families. For example, it is helpful to have a case manager present if the meeting will include discussion of complex discharge planning. Roles of members vary between institutions and even between care units, and may shift with the needs of a patient and family. A brief meeting of clinicians can clarify roles.

Anticipation: When and Where

Choosing a time and place that will not be interrupted can be a challenge but is vital for creating a sense of safety for patients and families. When possible, allow the patient or family to have a level of control over timing. If communication feels forced, trust may be damaged permanently. For cases with a great deal of clinical information or complex psychosocial barriers, begin conversations early, and choose a quiet, neutral setting where participants can sit comfortably.
Anticipation: How to Communicate

Communication aides such as telephonic or live interpreters, or an audio assistive device for a hearing-impaired participant, should be considered during the planning process, and techniques for use should be reviewed. For meetings that will address a new diagnosis, it may be beneficial to print information related to the patient’s condition. For some types of illness, such as a precariously positioned tumor, allowing patient/family to view images with support from a clinical team member to assist in interpretation. Use available resources, such as white boards or electronic devices, which can help convey information or display images.

When multiple providers participate, a brief discussion of roles and goals is recommended. There is variability in the role of the physician in discussing end-of-life decisions in the ICU [24]. Depending on the level of certainty about medical options and prognosis and patient/family preferences, communication strategies for shared decision-making may emphasize paternalism or patient autonomy [8]. Mindfulness to one’s own agenda and feelings is also helpful prior to entering a family meeting. Many providers are trained to have awareness of body language, eye contact, tone, and pacing of their speech. Just as clinicians must wash their hands to avoid bringing germs to the patient’s bedside, they must take a moment to reflect on what emotions they carry. Such techniques have been shown to improve satisfaction with care [25]. Practitioners who enter the patient’s or family’s space carelessly or fail to maintain a professional appearance and countenance can inadvertently sabotage the clinical encounter before it even begins.

The Goal-Setting Conference

Step 1—Choose the Right Setting: While the team cannot always control availability of quiet conference areas, clinicians can inquire about the comfort level of patients and families and make every attempt to optimize it—offering a bathroom break, a warm blanket, or water before serious discussions. Chairs and tissues can be moved to a private space to prepare for discussion. Remove distractions from the setting, such as turning off televisions, silencing non-essential alarms and phones, and placing a sign on the door to request privacy, and warning if an interruption may occur. For meetings that include the patient, sit at eye level and encourage others to be seated. If the patient is incapacitated, determine with the family whether the meeting should be held with the patient present; if so, portray respect and acknowledge the patient’s
guiding “voice,” even if s/he is unable to participate.

**Step 2—Make Introductions and Share Intentions for the Meeting:** While healthcare team members can prepare extensively for a family meeting, family members may have only moments to understand who is going to be speaking to them and why. Team members should be introduced and their roles explained. Terms like “resident” or “attending” may be meaningless to those without a medical background. Providing business cards of team members and offering materials to write down information can reduce distress. Some intensive care settings use brochures to explain the concept of family meetings [10].

Shaking hands, making good eye contact, offering a gentle smile, and bowing the head slightly can demonstrate respect, and sitting down sends a message of being willing to give time and attention [26]. Asking about proper pronunciation of patient’s name or whether a nickname is preferred signals that the patient will be treated as a valued individual.

**Step 3—Assess Patient/Family Understanding:** It is easy to assume that patients or families “should” understand the diagnosis or prognosis based on prior conversations or the amount of time that a patient has been ill. Only by asking patients/families to share perspectives can the clinician gain insight into what the patient or family know. When traumatic events have occurred, the act of telling the story to an empathetic clinician helps the patient and family to accept what has occurred and improves satisfaction with care [27]. Ask about the patient as a person—goals, values, passions—in addition to the clinical summary.

Open-ended questions should be used to explore the patient or family’s perception, resisting the urge to assume that broad comments such as “he’s really sick” mean the same thing to everyone. For patients with chronic illness or frailty, inquire about baseline function. A technique called “ask-tell-ask” reminds clinicians to respond with questions rather than commentary. “Can you tell me more about that? I want to make sure I understand” is a simple yet empathic question. It is the feeling of being listened to that correlates with positive impressions of the clinician [27].

Allowing the patient or family to speak first allows the health professional to carefully assess factors such as emotional readiness to hear difficult information or make decisions, patient and family’s health literacy, culture, any existing conflict within the family, and perspective on illness. Asking “Can you tell your biggest concern?” of all participants helps to focus the narrative and can elicit conflicts that may exist within the family. The attention of the clinician in lending a sympathetic ear is therapeutic [28]. If the topic of concern will not be covered in the meeting, the clinician can at least validate it and provide reassurance that the issue will be addressed in the future.

**Step 4—Give a Concise Medical Review in Clear Language:** A
clinician summary can add recent events or details that inform the decision at hand and, by repeating back elements of the patient/family summary, events are placed in context. It can be helpful to ask what level of information is preferred: “Some families like a lot of detail about the clinical side, while others want to focus on the big picture—do you know what you prefer?” With highly sensitive information, it can be helpful to get permission to talk about the topic before proceeding, and this allows patient or family to prepare for difficult news: “I’m afraid some of the news about his current condition is concerning. May I tell you about my concerns?” The clinician should avoid jargon and use slow, even speech with frequent pauses to confirm understanding. Many people do not feel comfortable interrupting a clinician to ask for clarification. If a medical term is introduced, inquire about the patient/family’s understanding of the term. Patients and families may also need explanations related to the nature of care in the ICU and common procedures.

**Step 5—Allow Silence and Respond to Emotion:** Response to emotion is critical at every point in the interaction. Discomfort with strong emotions is common, and failing to respond appropriately to emotions early in the interaction will limit the patient and family’s trust in the clinician. Dire news is often difficult to accept and the perception that the clinician does not care provides a tempting reason to discount clinical opinions. For the medical caregiver, years of training emphasizing the importance of clinical knowledge and detail can create a reflexive desire to present more medical information than is valuable. Moments of silence often are vital to allow patients and families to process information. Well-intended efforts to reiterate clinical information may fall on deaf ears and hinder efforts by the patient or family to express themselves. “I feel like I should pause here for a moment—this can be a lot to take in” gives permission for patient/family to express emotion or their inability to continue the conversation. Family members who have suddenly lost eye contact or physically withdraw (leaning back, looking away, bowing the head, or crossing arms) may be indicating the need to pause. Asking if a break is needed, leaning in, or—if culturally appropriate and natural to the clinician—reaching gently forward to touch the other person are subtle ways to offer support.

Techniques for responding to emotion are summarized in the mnemonic NURSE (Naming, Understanding, Respecting, Supporting, and Empathizing). In the concept of naming emotion, the clinician begins by taking a step back to identify what emotion is being expressed. It is important to notice that anger may actually be rooted in another feeling, such as fear or shame. Rather than making a declarative, somewhat presumptive statement such as “you seem angry,” normalize the emotion by saying “sometimes people begin to feel angry after talking about something like this.” The same subtlety is important with Understanding.
“I understand how you feel” may sound presumptuous, but saying “I can only imagine what this must be like for you” shows that you understand the complexity of the situation while trying to imagine what the other is going through.

Sadness and grief are common emotions in goals of care discussions. Tears may be a common response to difficult news and, while it may be uncomfortable to sit quietly, it is often the best response. Expressions of anger, frustration, or contempt can be unpleasant to hear. It is important to listen without defensiveness for areas where something can be done to allay the cause of the anger. Resist the urge to either make pacifying statements or become angry yourself, exhibit non-threatening body language, and speak calmly to prevent anger from overwhelming the interaction.

Anger is often secondary to other emotions, namely fear and guilt; gently identifying the sources of these underlying emotions can help defuse the anger. Families may fear that care at home was not adequate, that “signs” were missed, and fear future guilt and blame if the patient does not survive. Emphasizing that clinicians share in the lack of control over irreversible illness reduces guilt and builds the team’s partnership with family members to care for their loved one—especially if they cannot collectively “fix” the situation [29].

Supporting people through times of strong emotion requires empathy and non-abandonment. Showing sadness when giving bad news with statements of emotion (“I am worried that your body is not improving with treatment”) helps the patient and family to absorb the nature of the news. Clinicians who remain upbeat when giving bad news leave families thinking that the news was “mixed” due to incongruence of message and messenger, while those who withdraw without emotional expression add confusion and feelings of abandonment.

Patients and families faced with dire circumstances may still express hope, which requires a sensitive response from clinicians. Immediately discounting an outcome for which patients express hope can damage trust, yet it is imprudent to offer false hope in the form of non-beneficial treatments. An effective approach can be to simultaneously “hope for the best and prepare for the worst,” which allows the team to acknowledge the patient and family’s hopes while setting the stage for end-of-life planning. Family meetings allow everyone involved in a patient’s care to process strong emotions, grasp medical realities, and find hope in shared and realistic goals.

Step 6—Discuss Prognosis: Prognosis is extremely important for
guiding care decisions, yet is often not discussed explicitly due to clinical uncertainty, assumptions about awareness, and inclination to avoid uncomfortable topics. Keys to prognostication include formulating prognosis on the basis of medical facts and specialist input as needed; inquiring how much detail the patient and family desire; giving a range of times and probabilities, while acknowledging uncertainty; reassessing prognosis periodically with the patient and family; and responding empathically to emotion. Table 34.2 outlines a useful framework for formulating and communicating prognosis.

The following table illustrates several aspects in the formulation (foresee) and communication (foretell) of prognosis. In utilizing these steps, the clinician begins with the primary illness including its current stage and complications. It is known that functional status is a significant factor affecting survival in advanced or terminal illnesses. There are also some symptoms and tests that are incorporated into prognostic models as noted. Furthermore, although there is variance in clinicians’ ability to predict survival, it remains valuable as one incorporates the prior information into the experience and judgment of the physician to arrive at a reasonable prognosis. How this is shared with the patient and family depends a lot on what their goals and hopes are as well as how much/little they want to know.
Rather than giving a specific estimated time of survival, it is prudent to frame the discussion within a range of possible times and their probabilities, given the fact that no one knows for sure and a wide variation in what could happen for this individual. That is, prognostic tools provide a population-based set of statistics but which cannot readily reflect the illness trajectory of any one patient. Finally, one needs to review and reassess the patient from time to time to revise the prognosis, as it is a process, not a proclamation. Ultimately, “staying connected” throughout the final trajectory is in general what is most appreciated.

PPS, Palliative Performance Scale; KPS, Kamofsky Performance Scale; PaP, Palliative Prognostic Score; PPI, Palliative Performance Index; ECOG, Eastern Cooperative Oncology Group performance status; SEER, surveillance epidemiology and end results; SHFM, Seattle Heart Failure Model; CCORT, Canadian Cardiovascular Outcomes Research Team; CHESS, changes in end-stage symptoms and signs.

“Prognosis” or “recovery” can mean very different things to different people; such terms should be qualified in order to avoid confusion. For example, a patient with end-stage dementia may have a good prognosis to survive to ICU discharge, while having a grim prognosis overall. Without qualifying statements, families may perceive being told conflicting information, halting their ability to make decisions and raising questions about the motives or competence of medical caregivers. It is important to understand that “prognosis” means more than survival to most people—that is, they hope to know if their loved one will be close to the same person they were prior to the recent illness. While uncertain, the team should estimate the likelihood of a patient’s abilities to speak, walk, eat, recognize their families, etc., when discussing prognosis and treatment options with families.

Many patients with chronic critical illness have survived near-death experiences in the ICU; thus, family members may challenge the news of poor prognosis. In this situation, it can be helpful to reframe (“we’re happy that your loved one has beaten the odds so far”) and examine the “big picture” of the patient’s illness trajectory (see Fig. 34.1). With compassionate and honest discussion of the illness trajectory, the team can “hope for the best and prepare for the worst” with the family as they face critical milestones of decision-making. The simultaneous acts of relationship-building and information-sharing build trust over time and allow the team to make medical recommendations to alleviate the burden of decision-making on grieving, stressed family members.
If a patient and family are aware of a grim prognosis but steadfastly choose to pursue aggressive treatment, simply reiterating the facts about prognosis may be unhelpful. Instead, compassionately exploring underlying factors such as family dynamics, cultural beliefs, and spiritual distress can be illuminating, and can lead the interdisciplinary team toward finding ways to partner with the family on a mutually acceptable outcome (see Tables 34.3 and 34.4).

**Step 7—Explore Goals and Priorities:** As discussed above, it is possible to express sincere hope for the patient to recover while also explaining the limitations and burdens of intensive care [30]. Understanding that surrogate’s role as spokesperson for the patient’s values and preferences (rather than “decider”) not only ensures the appropriate ethical framework, but also reduces pressure on the surrogate. Questions such as “Given these circumstances, what would your loved one want us to focus on?”; “If he/she could hear the discussion and see our efforts, what concerns would be most important?”; or “What would he/she be hopeful for? What would be his/her greatest fear?” Because words like “recovery” and “improvement” are subjective, ask for clarification and explore the reasons behind preferences. This prevents miscommunication and also can prompt patients and families to more deeply explore feelings about illness and treatment. It may help to ask about the patient’s approach to prior health or major life challenges. What core values were revealed? When has the patient been willing to make major changes in his or her life? If rapport and shared understanding exist, a clinician can not only present options, but make patient-centered recommendations.

**Step 8—Present Broad Care Options:** When the patient and family
have fully understood the patient’s current condition, existing treatments, and prognosis, it is possible to discuss broad options for care. Best, worst, and “most-likely” case scenarios may be discussed. Discussing specific care options without context can lead to contradictory, poorly designed care plans.

On the basis of the articulated values and the clinical condition of the patient, the care team may offer goals such as a trial of treatment to promote recovery to baseline function, improving quality of life, surviving to witness a significant family event, improving comfort, or creating a more peaceful environment for patient’s death. Using techniques described in earlier steps, the clinical team can draw out patient/family perspective and respond to emotion during this process, in hope of prioritizing goals. Reassurance of the team’s commitment to attend to the patient’s comfort and dignity should be emphasized regardless of other goals.

Goals such as “hoping for a miracle” and “doing everything possible” should be further explored, examining the role of healthcare and the level of quality and quantity of life that is acceptable to the patient. Because feelings of guilt are common, it is helpful to emphasize that we only “choose” where to focus our efforts, we do not “choose” for a patient to die. While decision-making is shared, medical care in the ICU is ultimately the responsibility of the medical team.

**Step 9—Translate Goals into a Care Plan:** After reaching a shared understanding of clinical condition, prognosis, and patient-centered goals, the medical team makes recommendations for a care plan. Patients/families who have expressed desire for detail appreciate thorough descriptions of recommendations, while others prefer to feel that care is exclusively under the control of the medical team. Plan for management of physical, emotional, social, and spiritual needs of the patient and family. Rather than listing measures to be withdrawn or withheld, first emphasize the care that will be provided. Framing the withholding of a treatment as a means of protecting the patient from trauma emphasizes that the goal is not to “give up” but to honor the patient’s condition and values.

Some patients or families request aggressive treatment in spite of a poor prognosis. If the patient/family will not follow medical advice, suggest planning for the most likely outcome (e.g., prolonged life support). Emphasize the resulting reduced ability to communicate preferences and that the treatment ultimately cannot prevent death. If there are repeated requests for non-beneficial care, the team should consider consulting palliative care and ethics for assistance (see Tables 34.3 and 34.4 on Managing Conflict and Case Example).

**TABLE 34.4 Case—Managing Conflict**

A 73-year-old Korean woman with metastatic gastric cancer is transferred to the ICU for management of sepsis. The hospitalist caring for the patient over the last week reports that the patient’s son has “taken over” and has not been listening to staff attempts to discuss patient’s poor prognosis. The physician feels the patient is dying and recommended against ICU transfer, but acquiesced to the son’s wish. The patient requires pressor support and has multiple possible sources for infection. She is grossly edematous, with pressure ulcers and bruises from multiple needle sticks. She is pancytopenic as a result of recent chemotherapy, prolonged illness, and nutritional deficits. ICU caregivers report the patient is in pain. Although she speaks limited English, the patient tells staff at times that she wants to die. Her son, who continues to work full time, is listed as the primary contact in the medical record, and the patient and her husband defer all decision-making to their son. When the son visits with his pastor, he responds to information about her poor prognosis by suggesting the only option is to “pray for a miracle.” The son insists that the patient’s oncologist has said that his mother’s cancer is “treatable.” Nurses and other staff caring for the patient are feeling angry and uncomfortable about her care and interpret the son’s behavior at the bedside as “cold” and “micromanaging.”
Next steps and strategies:

1. ICU team huddle to clarify medical facts (including a conversation with the patient’s oncologist); acknowledge staff emotion and distress; consult with social worker, chaplain, and medical interpreters who have worked with the patient and family to share insights on family dynamics and spiritual and culture issues.

2. Schedule a family meeting for a mutually convenient time. Negotiate who should be present (patient, her husband, son, pastor, medical interpreter, ICU team) and what to discuss (“we want to review her situation and figure out the best way to care for her going forward”). Use structured approach from Figure 34.1 to assess their understanding; respond to emotion; share difficult news about prognosis; explore hopes, fears, and goals; and create a plan on the basis of shared decision-making.

3. Offer spiritual and emotional support, and invite the patient’s pastor to pray (including at the start or the end of family meetings). Ask the patient and family to teach the ICU team about their culture and faith traditions and how they may affect their coping and decision-making.

4. Allow time for the patient and family to absorb information and process emotion, and encourage them to spend meaningful time together as a family. If necessary, agree on a time-limited trial of interventions with specific goals (i.e., IV antibiotics for 5 days, with the goal of resolving the need for vasopressor support).

Outcome:

First meeting: At first, the patient’s son appeared angry and suspicious and asked to meet with the ICU team outside his mother’s room. He admitted to feeling overwhelmed by his mother’s illness, as well as his own family and work responsibilities. As an only child, and as the most proficient English-speaker in his family, he felt protective of his elderly parents. They find hope and solace in their faith and lean on their pastor for guidance. The son worries what will become of his father, who faces his own health problems, after his mother dies someday. The son listens to the physician’s assessment and news of poor prognosis, but says he still hopes for a miracle. The group negotiates to meet the next day at the patient’s bedside, with the husband and pastor present to continue the discussion.

Second meeting: The pastor is invited to pray, which is comforting for the patient and family. The ICU team follows the same structured approach (Fig. 34.1), but this time assessing the patient and husband’s understanding, and her goals and priorities. The patient acknowledges in front of her son that she is dying, and her faith in God supports her. The son says he doesn’t want her to suffer, but can’t believe “there isn’t anything else to treat her cancer,” despite the team’s discussion with her primary oncologist who confirms this.
Third meeting: The ICU team arranges for the oncologist to call the son directly on the phone, and instead he is able to visit the patient and family the next day. The ICU team and oncologist express their caring and concern and reiterate that she is dying from progressive, incurable cancer. They stress how they will work to ensure excellent end-of-life care, introduce the concept of hospice, and give the family time to think. A few hours later, the son asks the team to arrange hospice care at his home and requests help in obtaining a family medical leave from work. The patient’s oncologist remains as her attending physician under hospice care, and she is discharged the next day after equipment and medications are in place at the son’s home.

Concluding the interaction with a review of the next steps in care can help participants recall important points. Next steps should include plans to address any areas of uncertainty or conflict. Statements such as “we will always care for your loved one, no matter what happens” provide reassurance of the ICU team’s treatment of the individual, not the disease [31]. Affirming the decisions of the family or patient and offering anticipatory guidance can address likely future scenarios [32]. Closing the discussion with a follow-up plan and ways to contact the care team reassures the family of ongoing support.

**Step 10—Document and Debrief:** Clinician documentation ensures patient safety and quality of care. A carefully crafted progress note, documenting not only time spent but the level of preparation, the participants, the role of the patient (i.e., patient capacity or desire to participate), the context of options discussed, broad goals, and next steps can provide vital information for members of the medical team. Good documentation protects the patient and family from “starting anew” with each caregiver. Documentation provides a medical/legal record of the quality of the care provided. In addition to the patient medical record, the outcome of a family meeting—even if the outcome is a lack of consensus—ideally is discussed during a team meeting or hand-off with relevant health professionals. Caregivers may experience moral distress if the role of the care that they provide is not placed in context. Discussion among providers following a family meeting can also help staff to process the emotions of the event and to recognize opportunities for improvement.

---

**Bioethical Principles**

The ultimate irony of American health care: the growth of limitless technology coupled with resources that are limited [33].
The ever-evolving technologies available in the ICU allows medical teams to save and maintain lives in circumstances that would have been unthinkable years ago. These new technologies are exciting and hopeful, but often raise complex ethical issues. Decisions about when to use medical technology and resources can create moral dilemmas for clinicians as well as for patients and their families. These ethical debates can dramatically enter the public arena; for example, Americans witnessed intractable conflict within the family of Terri Schiavo regarding her prognosis and decisions about artificial nutrition, as well as the legal and political battles surrounding her case [34].

The American Medical Association first published a code of ethics in 1847. It wasn’t until the mid-1900s that the concepts of autonomy and self-determination entered the discussion of medical ethics, stemming from historical disregard for patient rights and frank abuse of vulnerable populations, including discrimination of minorities and women, involuntary human experimentation during World War II under the Nazi regime, and the Tuskegee experiments [35].

The Patient Self-Determination Act, passed by the U.S. Congress in 1990, mandated patient autonomy as a guiding principle of medical decision-making. This law requires health care institutions to ask patients whether they have an advance directive. The institution must also record patient preferences in, and offer processes for completing advance directives if they have not yet been done [35]. There is controversy about whether this law is effective as advance directives do not address multiple specific medical situations and are difficult to use when prognosis is not clear.

The two types of advance directives are (1) “instructional directives,” which provide guidance for caregivers, health care agents and representatives when making health care decisions for patients by way of substituted judgment and (2) “proxy directives”, which name a patient’s health care agent. Examples of instructional directives include living wills and the Five Wishes document. Proxy directive examples include health care durable power of attorney [35].

While autonomy is a cornerstone of medical decision-making, it is not the only ethical principle guiding complex care decisions in the ICU. Other bioethical principles include beneficence, nonmaleficence, and justice (see Table 34.5 for definitions and examples). These principles can help inform discussions among patients, families and the ICU team within the context of culture, faith, personal values and family dynamics. The Fifth International Consensus Conference in Critical Care issued a
consensus statement on ethical principles in the ICU, and emphasized a patient-centered approach with the ultimate goal of acting within patients’ best interests [36]. Ideally, this is accomplished through shared decision-making among the patient and family (who are experts in the patient’s values and goals) and the ICU team (who are the medical experts on prognostication and viable therapeutic options).

### TABLE 34.5 Bioethical Principles in the ICU

<td>Distributive Justice</td>
<td>Equal and fair distribution of resources</td>
<td>ICU care is costly and may significantly prolong the dying process in patients with irreversible conditions, which diverts resources from other patients.</td>
</tr>
</tbody>
</table>

Distributive justice is a core ethical principle, but is difficult and controversial to navigate at the bedside. While discussions about inappropriate use of resources and disproportionate care occur in the ICU [37], the principle of justice should be utilized in policy decisions on the care of all patients in order to minimize partiality and bias. Some hospitals have already determined or are beginning to discuss how to allocate resources in the event of a natural disaster (e.g., Hurricane Katrina) or terrorist attack.
Decision-Making Capacity and Substituted Judgment

In order to exercise autonomy, patients must have the capacity to make informed, reasoned medical decisions based on their values. Their capacity can be impaired by multiple factors, including acute illness, multiple medications, and chronic conditions [38]. Critically ill patients also suffer from varying degrees of hypoxia, hypotension, multi-organ dysfunction, and sepsis. Studies show that patients with compromised capacity to make medical decisions have an increased risk of mortality as well as increased cost of care [38]. In a review of 25 national studies using an array of assessment tools, the prevalence of incapacity among critically ill patients was significant: physicians missed 58% of patients who lacked decision-making capacity [39]. Physicians practicing critical care medicine need to understand how to assess a patient’s capacity for medical decision-making. Although most physicians lack any formal training, a structured framework for assessing capacity can help guide a skilled evaluation at the bedside (see Table 34.6) [40].

Any physician—not necessarily a psychiatrist—can make a determination of a patient’s decision-making capacity. Initially, capacity should be assessed when patients refuse a recommended procedure or treatment. If patients are amenable to proposed therapies, they are much less likely to have their capacity challenged. In situations where the benefits of an intervention outweigh the risks, a patient must meet a higher threshold for capacity in order to refuse the proposed procedure. If a patient is refusing a high-risk, low-benefit procedure, the threshold for capacity is lower [41].

The term “capacity” differs from competence. Only a judge can declare someone incompetent and legal standards for competence vary by state. A person deemed incompetent has more “general limitations” on his or her rights [41]. By comparison, capacity is both temporal and situational [39]. Capacity may vary, depending on the current medical condition of the patient. A patient may have capacity for simple, straightforward choices but not for complex decisions. In addition, cognitive impairment does not automatically imply a lack of capacity for all medical decisions. Assessment of capacity is warranted when patients have changes in their baseline mental status, are refusing recommended treatments, or have underlying conditions putting them at risk for impaired decision-making [42].

Of note, the dynamic and complex nature of the ICU also poses an increased risk of “pseudo-incapacity,” which occurs when patients do not understand their situation due to poor communication, such as excessive use of medical jargon, primary language barriers and/or low health literacy. Decision-making capacity can be enhanced by treating underlying medical conditions, ensuring clear communication in the patient’s primary language and educational level, and inviting a trusted confidant to help the patient cope with fear and anxiety when trying to process information.
Once a determination is made, it is important to document the assessment, including the use of any standardized evaluation tools. If a patient lacks capacity, the physician should invoke the patient’s designated health care proxy. The proxy should use “substituted judgment” to make decisions on behalf of the patient, based on the patient’s values and previously stated preferences. However, if a patient’s preferences are unknown, the surrogate should work with the ICU team to understand the medical situation and act in the patient’s best interests [43]. If the patient does not have a health care proxy, most states have established a hierarchy to determine a surrogate decision-maker; in general, the priority is the spouse, followed by adult children, parents, siblings and other relatives. If no surrogate decision-maker is available, the patient will require a court-appointed legal guardian for medical decision-making based on substituted judgment or, if substituted judgment is unknown, based on the best interests of the patient.

Withholding and Withdrawing Therapies

The decision to limit life-sustaining therapies (LST) prior to death in the ICU is difficult and complex. It is also a common practice, occurring in 74% to 90% of ICU deaths [44]. These decisions are influenced by many factors, including extent and severity of illness, prognosis, expected quality of life, perceived level of patient’s suffering, prior health care experience, resource availability, family dynamics, and cultural and socioeconomic backgrounds [45].

From a bioethical perspective, there is no difference between withholding versus withdrawing a treatment. Patients, or their surrogate decision-makers, have the right to refuse treatments such as life support, cardiopulmonary resuscitation, and artificial nutrition/hydration before or after they have been started [46]. However, ICU clinicians report in surveys that withholding and withdrawing therapies “feel” different. This discomfort may arise from the perception that withholding a therapy is passive (by not interfering with a natural dying process), while withdrawing a therapy is active (by altering a course of potentially life-prolonging treatment) [46]. These perceptions can provoke feelings of anxiety and moral distress. As a result, it is paramount that ICU clinicians gain knowledge and expertise in addressing patient, family, and ICU team distress over these bioethical decisions.

After skilled discussions about prognosis and goals of care, clinicians and family caregivers may decide to proceed with an acute withdrawal of
LST for an imminently dying patient. In other cases, seriously ill patients may be gradually weaned from intensive care—sometimes referred to as “no escalation of care” [44, 47]. Under this paradigm, the decision to continue or discontinue specific treatments is determined on an individual basis by the ICU team and the patient’s decision makers. Based on a few observational studies, the “Do Not Resuscitate” (DNR) order is often the first step in limiting LST, preceding death by 1 to 2 days. Additional interventions including dialysis, vasopressors, laboratory and diagnostic studies, blood transfusions and antibiotics are also likely to be discontinued.

In contrast, artificial nutrition and hydration are initiated in some cases despite “no escalation of care,” probably reflecting cultural beliefs by families or physicians that these therapies are more palliative than life-sustaining [44]. Decisions to withdraw this care can be controversial, and many families and caregivers view it as nurturing and vital for a dying patient. Families should be counseled on physiological changes during the dying process, including the loss of appetite and thirst, and the unintended consequences of fluid overload, including anasarca, pulmonary edema, ascites, secretions and incontinence with skin breakdown. In addition, there may be analgesic and anesthetic effects of dehydration, mediated by ketones and endogenous opioids [48]. It is important to reassure families that their loved ones are dying from their underlying disease and not from “starvation.” As appropriate, families should be offered the opportunity to participate in other expressions of caregiving, such as providing mouth care, bed baths and hand or foot massages.

Mechanical ventilation is usually one of the last life-sustaining treatments to be withdrawn, and occurs among only half of the ventilated patients who die in the ICU. Factors influencing the decision to withdraw mechanical ventilation include physician prediction of a <10% likelihood of survival, physician prediction of severely impaired future cognitive function, and the physician’s perception that the patient did not want life support [49, 50].

It is important to emphasize that time to death after withdrawal of mechanical ventilation varies widely, and that some patients have survived to hospital discharge [49]. In one study, half of patients died within 1 hour, the majority died within 10 hours, and some patients survived 7 days until death [50].

There is no evidence supporting a specific approach to the withdrawal of mechanical ventilation, but clinicians should consider a patient’s level
of consciousness when managing symptoms [46]. It is important for families to know that brain-dead patients can exhibit dramatic movements (the “Lazarus sign”) caused by the firing of spinal motor neurons in response to acute hypoxia. For patients who are comatose and unable to experience distress, clinicians can rapidly remove airway and ventilator support. If there is any concern that a patient may feel pain or anxiety, clinicians can pre-medicate the patient with analgesics and sedatives.

Patients who are conscious or semiconscious are more likely to experience distress during ventilation withdrawal. In these cases, a gradual decrease of supplemental oxygen may have an analgesic effect by creating hypoxia with normal carbon dioxide levels, followed by decreasing the ventilation rate [51]. During this “terminal weaning”, the FiO₂ is reduced to room air and positive end-expiratory pressure is reduced to zero followed by assessment of patient comfort. Ventilator support is then reduced from baseline to zero, taking rarely more than 5 to 20 minutes [52]. There are limited data available to determine whether removing the artificial airway provides more patient comfort, but families are more satisfied if extubation occurs [47].

Another set of LST modalities include left ventricular assist devices and total artificial hearts (referred to as mechanical circulatory support [MCS]). The decision to deactivate these devices is controversial because deactivation can be a life-ending intervention. Recent guidelines state that discontinuation of MCS is equivalent to allowing a natural death when there is onset of irreversible medical problems. Examples include irreversible coma, circulatory shock, overwhelming infections, multi-organ failure, refractory hypoxia or catastrophic device failure. Under these circumstances, deactivation of the MCS is made in collaboration with the patient, family, ICU team, and the MCS team [53].

During and following withdrawal of LST, clinicians should be present to evaluate for signs and symptoms of distress that may require palliative interventions. The bedside clinicians should be capable of anticipating and addressing the needs of the patient and family [48]. Therapies should focus on comfort and symptom management, including antipyretics, anti-emetics, anti-epileptics, analgesics, sedatives, and/or anticholinergics to control secretions. If a patient has an automatic implantable cardiac defibrillator, it should be deactivated in order to prevent firing during the dying process. The benefits and burdens of routine ICU care (e.g., monitoring devices, wound debridement, and endotracheal suctioning) should be discussed and subsequently continued, limited, or eliminated as appropriate [48].

In order to foster a private and caring environment, the ICU team should remove visiting hour restrictions, remove patient restraints, lower the bedrails, and remove machines and monitors from the room as
appropriate. Families also want to be assured of their loved one’s comfort and have the opportunity to express emotions, stories, prayers and rituals.

The use of a standardized order set for the withdrawal of LST has been studied [54]. The order form includes four sections: (1) preparation for withdrawal of life support that included documentation for a family conference, discontinuation of labs, radiographs and prior medications, and completion of a DNR order; (2) a nurse-driven sedation and analgesia protocol; (3) protocol for withdrawing mechanical ventilation that focused on patient comfort; and (4) a set of principles to guide withdrawal of LST. The majority of physicians and nurses reported that the order form was helpful and that it resulted in an increased use of opioids and benzodiazepines for symptom management. Importantly, the intervention was not associated with any change in time from ventilator withdrawal to death, suggesting that the increased use of these medications did not hasten death.

Medical Futility

Advances in medicine have enabled critical care specialists to save lives. However, intensive care interventions can also prolong the dying process or, more often, sustain life under circumstances that would not be acceptable to the patient. Some of the most ethically challenging situations for ICU clinicians involve requests by patients and families for “futile” medical interventions.

Unfortunately, these conflicts are common. A study of ICUs in the United States revealed that roughly 20% of patients received at least 1 day of treatment that physicians defined as futile [55]. In a single-day, cross-sectional study performed in Europe, 27% of ICU clinicians believed they provided “inappropriate” (defined as excessive) care to at least one patient [56].

In the early 1990s, bioethicists and professional societies attempted to define the term “medical futility” and how to manage it [57–61]. Conceptually, futile care was divided into three categories: quantitative, qualitative, and physiological [62]. Quantitative futility occurs when the likelihood of an intervention benefiting a patient is exceedingly poor (i.e., <1% chance of success) [60,63]. Qualitative futility occurs when the benefit to quality of life produced by an intervention is exceedingly poor. Treatment that preserves permanent unconsciousness or dependence on intensive medical care may be considered qualitatively futile. Finally, physiological futility describes treatments that cannot attain physiologic goals [59]. For example, providing a fourth vasopressor for a patient in refractory shock will not achieve an improved blood pressure and thus would be considered physiologically futile.
Although futility policies have been developed across the United States, critics have argued that futility determinations are inherently value-laden [59,64]. There has been no clear consensus on the definition of futility due to the difficulty in establishing what defines “meaningful survival [65].” Recently, a multi-society statement recommended the term “potentially inappropriate” in describing treatments with only a small chance of benefit that are not justified on the basis of clinician judgment and competing ethical considerations. The term “futile” should be used only in the rare circumstances in which an intervention simply cannot achieve the intended physiologic goal [58].

Recent qualitative research examined why ICU clinicians may provide inappropriate care. In one survey, physicians were uncomfortable with death, viewed death as avoidable and sought to delay it, or perceived a patient’s death as a personal failure [66]. Other determinants included family demands, lack of timely or skilled communication, lack of consensus among the treatment team [66,67], cultural beliefs [68], legal pressures, and lack of prognostic certainty [66]. Inappropriate care has been associated with admission delays from the emergency department, delays in transfer of ICU patients from outside hospitals, and cancelation of patient transfers from other hospitals [69]. One study estimated the cost of inappropriate care as $2.6 million over a three-month period [55].

There is also the possibility that certain inappropriate medical interventions might pose risks to other patients [70]. For example, providing antibiotics to a patient who will not benefit may lead to increased risk for antibiotic-resistant organisms in other patients. In the era of pay-for-value, providing ventilator support to a patient who will not benefit increases the risk of ventilator-associated pneumonia. This “never event” might earn the hospital a reputation as a place with high infection rates, causing payers to withhold reimbursements, and limiting the hospital’s resources to treat other patients [70].

Role of the Ethics Committee

The American Medical Association strongly recommends ethics committee consultations in situations where there is conflict over goals of care and end-of-life issues [71]. Often the disagreements between parties in these situations arise from differing morals and values. The central questions underlying these disputes often include:

whether to pursue aggressive life-sustaining treatment in a seriously ill patient;
whether to accede to family demands to provide life-sustaining treatment; how to deal with competing family members and companions wanting to make critical decisions on behalf of the patient; and what to do for a seriously ill, incapacitated patient who has no surrogate decision maker or advance directive [36].

Hospital ethics committees do not have a mandated composition and structure. Typically, the membership may include physicians, nurses, hospital administrators, social workers, allied health professionals, chaplains, lay community members, residents and medical students, hospital legal counsel and at times a bioethicist [72]. It has been recommended that the make-up of the committee reflect “the diversity of cultures, socioeconomic status and public opinion that exist in the community served by the institution [73].” Clinical ethicists “act as facilitators of communication and decision making about the goals for care, while directing attention to the ethical considerations underlying such decisions [74].” The American Society for Bioethics recommended core competencies for members of ethics committees in their report, “Core Competencies for Health Care Ethics Consultation [36].” It is important for all members of the committee to have some training and education in the field of bioethics. In reality, however, approximately 40% of those who perform ethics consultations in the U.S. have had no formal training, and only about 5% have had any graduate training in bioethics [75]. In fact, the vast majority of those who actually perform the consultations are clinicians rather than those lecturing and publishing about ethics in the academic world.

The primary role of ethics committees is offering critiques and suggestions for policy development and review. In this area, ethics committees can review policies and procedures related to end-of-life care, resource allocation, brain-death determination, advance directives, DNR policies, or anything else relating to patients’ rights [72,73]. Final approval of hospital policy rests with the hospital administration in most cases, and the process of review is ongoing. As technology evolves and the health care system changes, there will be a continued need to update policies to help guide staffs and institutions.

Second, ethics committee members must not only address their own training but also educate other health care professionals and the lay community. This stakeholder education can take place in many forums: hospital grand rounds, ethics symposia, and lectures to students and staff [73].

The third most common function of ethics committees is clinical consultation. This has been defined as “a service provided by a
committee, team, or individual to address the ethical issues involved in a specific, active clinical case [75].” The exact process varies by institution but primarily involves reviewing ethical dilemmas in patient care. Typically, there are three consultation models: full ethics committee evaluations, small-team models, or individual consultant models. Of these, research has shown that the most common model used in the U.S. is the small-team model [75]. In one large study of more than 500 U.S. hospital ethics committees, the committees recommended a “single best course of action for 46% of cases, described a range of acceptable actions for 41% of cases, and made no recommendation for 13% of cases [75].”

At most institutions, anyone, including patients and families, can request a consult—submitted anonymously, if desired. Unfortunately, there are limited available data on the effects and benefits of ethics consultations. One randomized controlled trial showed that ethics consultations in the ICU decreased length of stay and time spent in the ICU for patients who did not survive to discharge [36]. For patients who survived to discharge, there was no difference in ICU days or overall length of stay. In addition, the study found that an ethics consultation was associated with cost savings of $3,000 to $40,000 per patient, the bulk of which resulted from the care of patients remaining in the hospital for 10 days or longer after the consultation [36].

The decision to consult ethics versus palliative medicine can be framed in several different ways. Ethics consultation is often requested when there are questions or conflict related to values in order to help identify morally acceptable options. Palliative medicine consultants assist patients and families in synthesizing complex medical information, understanding prognosis, eliciting their priorities and goals, and facilitating shared decision-making. The American College of Critical Care Medicine recommends the availability of both ethics and palliative medicine consultations to improve end-of-life communication in the ICU [71]. Ethics consultants are often thought of as “outsiders” and viewed as a neutral party. The palliative care consultant serves the interest of the referring physician as well as the patient’s interests and may be thought of as “clinical insiders,” bringing a clinically oriented opinion to a particular case [76]. Both of these positions can be advantageous at different times depending on the situation and the emotions involved. As with any specialty consultation service, the culture of an institution, available resources and historical framework help in deciding which specific consultation may be most appropriate.

Treatment of Last Resort—Palliative Sedation

Palliative sedation (PS) is the intentional lowering of awareness towards, and including, unconsciousness for patients with severe and refractory
symptoms, as defined by the American Academy of Hospice and Palliative Medicine (AAHPM). The following summary of the AAHPM’s position statement [77] describes this procedure and its ethical implications:

PS is reserved for extreme situations, and should only be used after all available options have been exhausted to treat refractory symptoms. As with any procedure, PS must have a specific indication, a target outcome, and a benefit/risk ratio that is acceptable to the medical team, patient and family. The level of sedation should be proportionate to the patient’s level of distress. Treatment of other symptoms must also be continued, since sedation may decrease the patient’s ability to communicate or display discomfort.

Palliative sedation raises ethical concerns when it significantly reduces patient consciousness to the degree that the patient is unable to substantially interact with others, does not have the ability or opportunity to change his mind, and is unable to eat and drink (thus potentially shortening survival in particular circumstances). Palliative sedation is ethically defensible when used (1) after careful interdisciplinary evaluation and treatment of the patient, and (2) when palliative treatments that are not intended to affect consciousness have failed or, in the judgment of the clinician, are very likely to fail, (3) where its use is not expected to shorten the patient’s time to death, and (4) only for the actual or expected duration of symptoms. Palliative sedation should not be considered irreversible in all circumstances. It may be appropriate, in some clinical situations when symptoms are deemed temporary, to decrease sedation after a predetermined time to assess efficacy, continued symptoms and need for ongoing sedation.

In clinical practice, palliative sedation usually does not alter the timing or mechanism of a patient’s death, as refractory symptoms are most often associated with very advanced terminal illness. Practitioners who use palliative sedation should be clear in their intent to palliate symptoms and to not shorten survival. Because patients receiving palliative sedation are typically close to death, most patients will no longer have desire to eat or drink. Artificial nutrition and hydration are not generally expected to benefit the patient receiving palliative sedation, however questions about the use of artificial nutrition and hydration should be addressed before palliative sedation is undertaken.

There is no clear consensus or scientific evidence regarding the most appropriate medication(s) to effect palliative sedation. As elsewhere in medicine, the agent should be selected based on safety, efficacy, and
availability [77].

Of note, opioids do not reliably achieve sedation. Palliative care clinicians often use benzodiazepines, sedating antipsychotics, barbiturates or propofol for palliative sedation, depending on the patient’s co-morbid symptoms and clinical response [77].
REFERENCES

2008.

Patients in the intensive care unit (ICU) experience a variety of distressing symptoms caused by critical illness and/or its evaluation and treatment. Effective symptom management improves patients’ abilities to heal from injuries, tolerate evaluation and treatment, cope with stress, and recover from severe illness or injury. This chapter reviews the management of common symptoms among ICU patients with severe illness or injury, including pain, dyspnea, nausea/vomiting, constipation, agitated delirium, anxiety, and depression.

PAIN MANAGEMENT IN PALLIATIVE CARE

Pain is a frequent and troubling symptom for patients with serious illness. ICU clinicians must have the knowledge and skills to effectively evaluate and treat the pain of critically ill patients. When pain is complicated and refractory, the ICU team should work with specialists from palliative care and pain anesthesia to formulate advanced approaches to complex pain. (For a complete and excellent discussion on pain assessment and treatment, see Chapter 3.) In addition, this section describes palliative care principles for the management of pain and offers pearls for clinical practice.
GENERAL PRINCIPLES

Pain is a multidimensional experience impacted by biologic, psychological, emotional, and social factors. Multiple studies show that pain perception does not always correlate with physical injury and that emotional pain or stress can activate the same brain structures as physical pain. Patients interpret sensations transmitted from nociceptors and peripheral and central nerves through their own personal mindset; in turn, these thoughts and emotions influence descending pathways from the brain to inhibit (or enhance) pain transmission through ascending neural pathways. When patients are faced with serious illness, physical pain inherently impacts multiple aspects of personhood (see Fig. 35.1). As a result, comprehensive pain assessment and management requires an interdisciplinary approach to address emotional, psychosocial, and existential/spiritual aspects of pain and suffering [1].
**Table 35.1** outlines general principles for effective pain management, including whole-person assessment and care. Regular pain assessments with a consistent tool (selected after consideration of cultural, literacy, and personal factors) allows patients and staff to partner for managing pain. In addition to tools that quantify the pain intensity and/or observed behaviors, the interdisciplinary team should consider the following aspects of pain and suffering in patients with advanced illness:

- Understanding what the pain means to the patient;
- Inquiring about past experiences of pain;
- Exploring the patient’s coping skills for pain and stress;
Learning about the patient’s knowledge, preferences, and expectations for pain management;
Screening for any concerns about the use of controlled substances, especially opioids (which might include a history of addiction and/or fears of becoming addicted and refusing opioids);
Assessing the impact of pain on the patient’s mental health, quality of life, and functioning (including the ability to work on rehabilitation).

TABLE 35.1 Pearls for Managing Pain in Palliative Care Patients

- Determine the underlying cause(s) and reverse what is treatable/modifiable;
- Perform structured pain assessments with a consistent tool;
- Work with interdisciplinary team to understand and treat the emotional, psychological, social, and existential/spiritual aspects of pain;
- Start low and go slow with medications in patients with altered absorption, metabolism, and excretion due to serious illness;
- Use IV route for pain crises, and premedicate before procedures;
- Understand pharmacokinetics of opioids and how to dose for continuous pain (based on half-life of drug) and breakthrough pain (based on time to maximum concentration in the serum);
- Utilize multimodal analgesia, including adjuvants, interventional modalities and nonpharmacologic approaches;
- Consider strategies to treat multiple symptoms simultaneously to minimize polypharmacy (i.e., corticosteroids for bone pain and nausea, antidepressants for neuropathic pain and mood);
- Monitor closely and adjust medications on the basis of analgesic response and side effects;
- Coordinate plan of care for pain management with outside providers if patient will be discharged out of the ICU.
Clinicians should always consider the pathophysiology of the pain and treat the underlying cause as possible (e.g., high-dose single-fraction palliative radiation for a painful bone metastasis). With pain medications, clinicians should understand and use pharmacologic principles to guide therapy, including (1) start low and go slow in frail, opioid-naïve patients; (2) use the intravenous route of administration for pain crises; (3) dose for breakthrough pain and procedures based on $T_{\text{Cmax}}$ (time to maximum concentration in the blood); (4) scheduled dosing for continuous or chronic pain based on $T_{1/2}$ (half-life of the drug); and (5) prevent and manage side effects. Clinicians should always consider multimodal analgesia and/or interventional techniques depending on the pain pathophysiology (e.g., anticonvulsants and/or antidepressants for peripheral neuropathy, or a celiac plexus block for epigastric pain related to pancreatic cancer). Studies show that opioids combined with adjuvants are more effective for neuropathic pain than opioids alone, and this approach reduces both the opioid dose and systemic side effects [2]. The ICU team should closely monitor and adjust the plan of care based on the patient’s responses, and when the patient is close to discharge out of the ICU, coordinate closely with the next provider who will assume responsibility for ongoing pain management.

Finally, there are special considerations for patients who are dying in the ICU. The dying process itself is not recognized to be inherently painful; however, if a patient has a history of pain and/or clear causes of new pain, then pain should be effectively treated [3]. Agitated delirium (see Delirium section) can be misinterpreted as pain, and if incorrectly diagnosed and untreated, can lead to escalating opioid doses with worsening agitation and hyperalgesia [4]. In general, dying patients should never be started routinely on narcotic infusions in the absence of symptoms (i.e., “start morphine sulfate 1 mg per hour IV, titrate to comfort”), as sound pharmacologic principles always apply. Indiscriminate narcotic dosing can lead to build-up of active metabolites when renal failure occurs, resulting in agitated delirium from opioid neurotoxicity and/or hastened death (Fig. 35.2).
FIGURE 35.2 Two roads to death [49].
MANAGEMENT OF DYSPNEA

Dyspnea is defined as “a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity [5].” More than 50% of patients report dyspnea during the months before death, and its prevalence increases as death becomes more imminent [6]. The underlying disease responsible for dyspnea seems to influence its prevalence and severity at the end of life. An observational study in Australia of 5,862 patients under hospice care showed that patients with a noncancer diagnosis experienced a higher prevalence and severity of dyspnea compared with cancer patients [7]. Patients with a primary respiratory disease were most affected. Surprisingly, even patients without an apparent cardiopulmonary condition reported a high frequency of shortness of breath (Table 35.2).

Mechanisms of Dyspnea

Currently, the mechanisms responsible for dyspnea are not fully characterized. Dyspnea is a result of the interplay between physiologic factors and psychological, social, and environmental elements [5]. Afferent impulses originate in, or are at least modified by, receptors located in the skin, chest wall, respiratory muscles and tendons, airways, lungs, pulmonary vessels, carotid and aortic bodies, and medulla. These impulses then activate the cortico-limbic region, which elicits a ventilation response. At any given moment, it is likely that multiple inputs are generated, transmitted through different pathways, and leading to a variety of uncomfortable respiratory sensations collectively described as dyspnea. Dyspnea occurs when a subject perceives an imbalance between respiratory demand and ventilatory response.

Treatment

As demonstrated by its high prevalence among patients under hospice care, alleviation of dyspnea at the end of life is often inadequate [7]. There is general agreement that the initial focus of management should be on treating the underlying disease process responsible for this symptom [8]. Nonspecific treatment of dyspnea should follow in situations of persistent shortness of breath. We have divided nonspecific therapies into the following categories: first-line therapies (recommended), second-line therapies (probably effective, considered for refractory situations), and interventions of unknown efficacy.

First-Line Therapies

Systemic (oral or parenteral) opioids are effective for the treatment of
dyspnea, and they are considered the primary therapies. Evidence for this therapy was derived from meta-analyses of randomized controlled trials (RCTs) of patients with cancer, chronic obstructive pulmonary disease (COPD), and other dyspnea etiologies [9–11]. Their mechanism of action likely involves depression of the respiratory drive and changes at the cortical level [5]. Although effective, the magnitude of their benefit is unclear. They can be associated with a variety of side effects including nausea, vomiting, constipation, and drowsiness. Respiratory depression has been a particular concern of this therapy. However, it has not been reported with the opioid doses used for treating dyspnea, including in patients with advanced COPD [9]. Morphine is the best studied opioid therapy. In nonacute situations, it is reasonable to start with a low dose (oral, immediate-release formulation) and transition to a long-acting dose once a steady state has been reached [5].

Second-Line Therapies

Dyspnea therapies in this group include interventions that have shown benefit from at least one RCT but for which positive effect was not consistently observed among other studies or when only small clinical trials were performed. They can be considered when dyspnea persists despite the use of opioids. These include noninvasive ventilation (NIV), fan, heliox, and inhaled furosemide.

Small clinical studies suggest that NIV might mitigate dyspnea for some patients. The best evidence is derived from an open-labeled RCT of 200 patients with end-stage solid cancer and acute respiratory failure who were randomized to NIV or oxygen groups for palliation of shortness of breath [12]. Patients of the NIV group demonstrated a faster improvement of dyspnea and used less morphine compared with the control group. In addition, one RCT showed an association between improved dyspnea and the use of NIV for cancer patients without acute respiratory failure [13].

Two other interventions that were shown to decrease dyspnea in single RCTs are the use of a fan directed to the face and heliox. The use of a handheld fan was associated with a reduction of dyspnea by an RCT of 50 patients with malignant and nonmalignant conditions [14]. A putative mechanism of action implicates stimulation of the trigeminal nerve by the cool air. It represents a low-cost and low-risk therapy that is widely available. Heliox was effective for reducing dyspnea and increasing walking distance in a phase II, double-blind, crossover RCT of 12 patients with lung cancer with dyspnea on exertion [15]. Its mechanism of action
could involve a decrease in the work of breathing by increasing airflow at sites on airway narrowing by virtue of its lower density compared with air.

Inhaled furosemide is another second-line therapy for dyspnea. Several small RCTs of inhaled furosemide have shown improvement of dyspnea. These studies included healthy subjects with experimentally induced dyspnea and patients with COPD. The largest of these studies was a double-blinded study that included 100 patients with COPD exacerbations that were randomized to inhaled furosemide or normal saline [16]. Most of these trials used a 40-mg dose of furosemide as a single or daily dose. The mechanism of action of furosemide is unknown but could involve desensitization of the respiratory epithelium.

The use of oxygen with the intent to alleviate dyspnea should be considered for certain subgroups of patients. RCTs of patients with cancer, COPD, and other conditions suggest that oxygen does not relieve dyspnea compared with medical air [10,17,18]. However, most of the subjects from these studies were either outpatients or had no respiratory distress. Thus, it is unclear if the results from these trials can be extrapolated to patients in an ICU with severe dyspnea or at the end of life. It is also unknown if medical air, used as placebo in these studies, could have exerted a therapeutic effect by cooling the nasal mucosa, for example. Until new evidence is available, we suggest considering the use of oxygen in patients with respiratory distress because it is a low-risk intervention with potential benefits. Oxygen should be provided to breathless patients with hypoxemia [5,8].
INTERVENTIONS OF UNKNOWN EFFICACY

No definitive large-scale RCTs of inhaled opioids have been performed. Systematic reviews and meta-analyses that primarily included patients with COPD and cancer suggest that inhaled opioids provide little or no benefit for the treatment of dyspnea [9–11].
GASTROINTESTINAL SYMPTOMS: CONSTIPATION, NAUSEA, AND VOMITING

Gastrointestinal (GI) dysfunction, although a frequent and important determinant of ICU outcomes, currently lacks formal definition and classification [19]. Furthermore, treatment of GI symptoms during an ICU stay is often guided by experience and not evidence, with treatment strategies being extrapolated from non-ICU inpatients, outpatients, and palliative care settings.

Nausea, vomiting, and constipation can be associated with acute exacerbations of chronic illness, acute and rapid presentations of disease, or secondary to the interventions and medications prescribed during a hospitalization. The incidence of constipation in the ICU ranges from 69% to 83% and diarrhea occurs in as many as 36.1% of patients [20]. In fact, the incidence of critically ill patients, including mechanically ventilated patients who have at least one GI symptom, is 59% [21]. Development of two or more GI symptoms is associated with higher mortality and longer ICU stay [22].

GI symptoms frequently lead to discomfort for the patient and create obstacles to providing medical care. Constipation may lead to difficulty with ventilator weaning, enteral feeding intolerance, and a longer ICU stay [22]. Furthermore, nausea and vomiting may hinder reaching nutritional goals by delaying initiation of enteral feeding and complicate medication delivery and absorption. Providing palliative care for these symptoms during an ICU stay can be offered simultaneously with efforts to extend life and treat underlying medical issues with an overall goal to improve quality of life.

**Constipation**

Constipation is defined as infrequent or absent bowel movements that occur with difficulty of passing stool. In most ICU studies, the time period was at least 3 days [20]. The causes of constipation during an ICU stay include immobility, dehydration, and metabolic causes such as hypercalcemia and hypothyroidism. Medications are also a frequent cause of iatrogenic constipation during an ICU stay, including calcium-channel blockers and anticholinergic agents. Vasoactive drugs such as
dopamine can cause constipation, and hemodynamic instability in the setting of hypoperfusion, shock, and endotoxin overproduction can decrease bowel motility. Opioids are regularly used for management of pain and sedation among critically ill patients and frequently cause constipation. The effect of opioids on the bowel includes reduced peristalsis throughout the GI tract, decreased intestinal fluid secretion, and increased intestinal fluid absorption resulting in constipation and the passage of hard stools [19].

Assessment

It is important to elicit a careful history, including the past medical history, the past abdominal surgical history, and prior bowel habits to establish whether chronic constipation was present or the patient has risk factors for constipation. Inpatient medications and medical interventions performed during the hospitalization must also be reviewed. The timing, quality, quantity, and frequency of stools since admission will characterize the degree of constipation. Some patients may present with unexplained nausea and vomiting. Abdominal pain may occur as the bowel attempts to evacuate hard stool. A physical exam, including abdominal and rectal examinations, is necessary. The abdominal examination may show firmness, distension, and the presence of hyperactive or hypoactive bowel sounds. Fecal impaction may be found on rectal examination. In some cases, fecal impaction may present as diarrhea with incontinence when fecal material higher in the colon is broken down into liquid form and flows past the mass. An empty rectal vault may suggest a proximal obstruction.

Patients with traumatic spinal cord injury often have neurogenic bowel, but clinicians may overlook it in nontraumatic etiologies such as multiple sclerosis, stroke, or cancer. In these patients, digital rectal and abdominal exams can help distinguish between upper motor neuron (a tight anal sphincter with peristalsis intact) and lower motor neuron lesions (a flaccid sphincter with no volitional contraction). In upper motor neuron injury, evacuation depends on stimulating the bowel wall digitally or with a suppository; by comparison, patients with lower motor neuron injury may need stool-bulking agents like fiber to control stool flow [23].

A plain abdominal radiograph can estimate the stool burden and differentiate between obstruction and constipation. In patients with continued symptoms and concern of alternative etiologies, computed tomography may aid in evaluation of small bowel obstruction, ileus, intra-abdominal abscess, bowel perforation or undiagnosed intraluminal or extraluminal abdominal masses.

Treatments
It can be effective to time medication use with a patient’s normal toileting schedule and take advantage of the gastrocolonic response with meals to improve outcomes. In general, a greater volume of stool causes luminal stretch and triggers peristalsis. Hydration and high dietary fiber content are advantageous for healthy, active patients; however, additional dietary fiber such as psyllium may worsen constipation and should generally be avoided for critically ill patients who are not well hydrated.

If constipation due to secondary causes is suspected, interventions aimed at treating and reversing underlying etiologies should be attempted. Drugs that inhibit gastric motility should be withdrawn and avoided when possible. If impaction is suspected, a digital rectal examination and manual disimpaction is advised. Pharmacologic therapies that utilize different mechanisms and combine oral and rectal interventions may yield effective results.

The early use of supportive therapeutic agents is important and can be initiated independent of underlying pathology and bowel habits (see Table 35.3). Laxatives increase intestinal propulsion and secretion, and their use in the ICU is to improve intestinal fluid balance by promoting water secretion and preventing excessive water absorption. Stimulant laxatives such as senna and bisacodyl increase intestinal activity and secretion. Bisacodyl is activated in the small intestine by the hydrolytic activity of endogenous esterases. Senna is activated by colonic bacteria in the colon. Osmotic laxatives include magnesium salts, lactulose, and polyethylene glycol (PEG 3350), which are marginally reabsorbed and produce softer stool with larger volume by drawing in water during bowel transit. Magnesium salts must be used cautiously in renal insufficiency as this may lead to magnesium toxicity. Lactulose passes unabsorbed into the colon where bacteria break it down, thus possibly causing bloating and abdominal cramping. PEG 3350 is not metabolized by bacteria, resulting in no production of intestinal gas. It does not lead to a loss of fluids or electrolytes across the GI tract and is well tolerated with high effectiveness. PEG 3350 is also available without electrolytes (Miralax), which can be combined with a liquid.

With chronic or opioid-induced constipation, best practice is to schedule daily laxatives for bowel...
maintenance (i.e., senna two tabs daily) and as-needed medications for rescue if no bowel movement in 48 hours (i.e., PEG 17 g daily or bisacodyl 10 mg PRN).

Enemas and glycerol suppositories soften stool and generate peristalsis. Enemas are available as warm tap water, mineral oil, or sodium phosphate. Sodium phosphate enemas should be used with caution among elderly patients as they may cause hypotension, volume depletion, and electrolyte loss [24]. Metoclopramide is a prokinetic agent that antagonizes dopamine receptors, and it can be used in constipation that has not responded to other pharmacologic interventions.

Opioid receptor agonists are frequently used for sedation and pain in the ICU. The GI effect of opioids on the gut involves the enteric nervous system, and the agonism of enteric µ-opioid receptors of the GI tract inhibits gastric emptying, increases pyloric muscle tone, and delays transit through the small and large intestine. Methylaltrexone is a peripheral opioid antagonist with limited ability to cross the blood–brain barrier and thus does not reverse centrally mediated analgesia. It is approved for treatment of opioid-induced constipation among patients with advanced illness and is effective for inducing laxation of palliative care patients with opioid-induced constipation where conventional laxatives have failed [25].

Nausea and Vomiting

Nausea, vomiting, and retching have distinct definitions. Nausea is a subjective sensation that precedes the need to vomit and may be associated with other symptoms including tachycardia, lightheadedness, diaphoresis, abdominal pain, and diarrhea. In contrast, vomiting and retching are objective. Vomiting involves expulsion of gastric contents after forceful contraction of abdominal musculature. Retching is contraction of the abdominal musculature in the presence of a closed glottis and no expulsion of gastric contents. Nausea may occur in isolation or precede vomiting and retching. Any of these symptoms in the most severe form may result in electrolytes imbalances, dehydration, and feeding intolerance with subsequent malnutrition.

Emesis is mediated by a complex interaction of afferent, humoral, and parasympathetic pathways. The vomiting center is located in the medulla oblongata and receives input from the chemoreceptor trigger zone (CTZ) located in the area postrema, the nucleus of the tractus solitarius, the GI tract, and the vestibular pathway. Dopamine, serotonin (5-HT), acetylcholine, histamine, and neurokinins are neurotransmitters involved
in emetogenesis that bind to the receptors of the vomiting center, CTZ, and GI tract. The vomiting center additionally activates efferent pathways to the cranial nerves, diaphragm, and abdominal muscles [26,27]. Altogether, the activation of these various components triggers emesis (Fig. 35.3).

![Diagram of the emetic pathway]

**FIGURE 35.3** The emetic pathway. CTZ, chemoreceptor trigger zone; Ach, acetylcholine; D₂, dopamine; GABA, γ-aminobutyric acid; H₁, histamine; 5-HT, serotonin; NK₁, neurokinin; CB₁, cannabinoid.

Primary causes of nausea and vomiting in the ICU include adynamic ileus, ketoacidosis, pancreatitis, liver dysfunction, Ogilvie syndrome and abdominal compartment syndrome. Secondary causes of symptoms are adverse effects from medications, shock, abnormal lab values, renal failure, intracranial lesions, increased intracranial pressure, heart failure, and nonabdominal surgery [19].

**Assessment**

Evaluation of nausea and vomiting in the critical care setting must involve patient assessment and corroboration of information from nursing staff. A thorough evaluation of the history, physical examination, laboratory, and radiographic data can frequently identify an etiology. Key components to assess are as follows:
Symptoms of nausea, vomiting, retching, reflux, diarrhea, distension, abdominal pain, regurgitation, and constipation

Timing, frequency, nature of the event (i.e., bloody or undigested food emesis), and the volume of gastric residuals if the patient is receiving enteral nutrition

The inpatient medication list, especially opioids, antibiotics, and chemotherapeutic agents

Physical examination including vital signs, fluid status assessment, abdominal distention, abdominal pain, and the presence of bowel sounds

Review of laboratory values and looking for evidence of organ dysfunction

Review of abdominal imaging

For example, the clinical assessment may reveal a pattern of delayed gastric emptying, which presents with intermittent nausea relieved by vomiting. Bilious or fecal emesis associated with abdominal discomfort and constipation or absence of bowel movements can suggest bowel obstruction. Constipation of the lower GI tract can precipitate nausea and is associated with use of opioids, sedatives, and intravenous catecholamines used for hemodynamic resuscitation. Ileus occurs after abdominal surgery, and general anesthesia also contributes to nausea among postoperative patients.

Treatment

A successful approach to managing the symptomatic patient incorporates thorough patient assessment, knowledge of the emetic pathophysiologic pathways, and a comprehensive treatment plan including pharmacologic and emotional support [26].

No guidelines exist for the pharmacologic treatment of nausea and vomiting for the critically ill. Published guidelines currently focus on chemotherapy-related and postoperative nausea management [27,28]. The occurrence of encephalopathy during critical illness may result in clinicians treating signs of emesis rather than symptoms. Although targeted antiemetic treatment blocks the neurotransmitters implicated in the underlying cause, empiric therapy may be necessary without a clear etiology, usually with a dopamine or serotonin antagonist [26]. (See
Table 35.4 for an example of an order set with targeted pharmacologic and nonpharmacologic approaches.)

**Circle antiemetic(s) below, based on etiology**

- Corticosteroid
  - Dexamethasone 4 mg PO/IV daily in AM
- Dopamine Antagonists (choose only one)
Metoclopramide and domperidone are dopamine (D₂) antagonists that work within the brain’s CTZ, as well as increase gastric emptying and decrease small bowel transit time resulting in gut prokinesis. In addition to D₂ blockade, metoclopramide activates 5-HT₄ receptors that mediate acetylcholine release, thus increasing upper GI motility. Extrapyramidal adverse effects can occur, which may be treated with diphenhydramine. Dose adjustment must be made with renal insufficiency and in elderly patients. Domperidone is not available for use in the United States.

Phenothiazines are D₂ antagonists but have broader activity than do metoclopramide, as they additionally block cholinergic and histamine receptors. These drugs have potent antiemetic activity, but are frequently associated with adverse effects including hypotension, sedation, dry mouth, and extrapyramidal effects. Prochlorperazine, promethazine, chlorpromazine, and levomepromazine are several phenothiazines that are available. Haloperidol is a potent D₂ antagonist used for the treatment of delirium and agitation in ICUs. Among terminal cancer patients, it is commonly used for the management of nausea and vomiting, and it has also been used for postoperative nausea and vomiting [29]. However, data are lacking for its use as an antiemetic for the critically ill. Adverse effect monitoring should include electrocardiograms for QT prolongation and observation for extrapyramidal side effects.
More recently, there has been interest in the atypical antipsychotic olanzapine for chronic nausea and chemotherapy-induced nausea and vomiting. Olanzapine works through multiple neurotransmitters including D₂, 5-HT₂, 5-HT₃, acetylcholine, and histamine and thus may impact many areas of the emetic pathway in complex, refractory nausea. In addition, olanzapine has five times the affinity for 5-HT₂ over D₂ receptors, resulting in lower extrapyramidal side effects [30].

The 5-HT₃ receptors are found within the vagus nerve, brain, and gut enterochromaffin cells. Several 5-HT₃ antagonists are available, including dolasetron, granisetron, ondansetron, and palonosetron. Their use is established for the prevention and treatment of nausea with chemotherapy and also in the postoperative patient [27,31]. Although this drug class is commonly used for the critically ill, clinical trials are lacking. This class of drug is also associated with prolonged QT interval and can contribute to constipation.

Glucocorticoids are effective in chemotherapy-related and postoperative nausea, as well as in malignant bowel obstruction and elevated intracranial pressure from brain tumors. If nausea and vomiting is suspected due to corticosteroid insufficiency during acute illness, treatment with intravenous corticosteroids should be initiated.
PSYCHIATRIC SYMPTOMS: DELIRIUM, ANXIETY, AND DEPRESSION

Delirium

Delirium is a common and often devastating complication of advanced illness, occurring among nearly 85 percent of patients during their final weeks of life [32]. Delirium, which can be hyperactive, hypoactive, or mixed, is associated with increased morbidity and can be a sign of impending death of terminally ill patients. The symptoms of delirium can cause significant distress for patients, families, and staff. Delirium can also interfere with the assessment and management of other physical and psychological symptoms, such as pain. This section will focus on key management principles of palliative care patients, including

1. making a timely diagnosis,
2. determining reversibility versus irreversibility of the underlying cause(s),
3. understanding prognosis and goals of care to guide workup and management,
4. educating families and caregivers about delirium, and
5. using nonpharmacologic and pharmacologic measures to keep a patient comfortable and safe.

For a complete discussion of diagnosis, workup, and treatment of delirium, please see Chapter 157.

Assessment

Unfortunately, delirium (especially the hypoactive form) is often misdiagnosed and therefore untreated in terminally ill patients. Due to its high prevalence, ICU teams should use a consistent, evidence-based tool for diagnosis and screening, such as the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC), which have been found to have a high degree of sensitivity and specificity in two meta-analyses [33]. Patients with advanced illness have multiple physiologic disturbances that can cause delirium, and many etiologies are irreversible in dying patients. However, there are common reversible etiologies as well, including constipation,
For determining reversibility of delirium, a clinician should review the patient’s principal diagnosis, comorbidities, prognosis, and preadmission and current functional status. It is essential to hold a family meeting (including the patient if he or she is able to participate) in order to explain the nature of delirium, explore patient’s goals and priorities, and weigh the benefits against burdens of further evaluation to elucidate the underlying causes (see Table 34.1 on structured family meetings of Chapter 34). Some patients, families, and ICU teams may agree on time-limited therapeutic trials and/or less invasive testing, especially if the results may allow an easy intervention that might reverse the delirium, reduce distress, or improve a patient’s quality of life. Among other cases, the patient and family may decline a therapeutic trial or workup based on poor prognosis and/or need for burdensome testing, and delirium becomes effectively irreversible [34].

**Prevention and Treatment**

The most effective way of managing ICU delirium is to recognize the risk factors and attempt to prevent the development of delirium. These modifiable risk factors include polypharmacy, environmental factors (such as noise and sleep interruptions), and social interaction with visitors and the health care team. Windows may be associated with lower ICU delirium prevalence, but only if they allow enough light and a dark–light cycle [35]. In addition to light deprivation, noise levels can be lowered to reduce delirium in the ICU, but this may in fact be quite difficult to achieve [36]. The risk of delirium can be significantly lowered by utilizing ear plugs for patients [37]. Early mobilization has been utilized to reduce both the incidence and duration of delirium in the ICU [38]. There is no recommendation for using a pharmacologic delirium prevention protocol [39]. Numerous studies have found that the use of dexmedetomidine in place of benzodiazepines or propofol results in a lower risk of delirium, but none have compared it with placebo [40]. The best chance for reducing the incidence of ICU delirium may be the implementation of care bundles, which include early mobility, measures to improve sleep and circadian rhythm, and protocols for interruption of sedation, spontaneous breathing trials, and delirium monitoring [41].

p. 326

p. 327
Once an ICU patient develops delirium, it can be challenging to treat the symptoms, especially if the underlying cause is not reversible. The goals of symptom management are to keep a delirious patient safe and comfortable, while supporting and educating the family. The interdisciplinary team should provide intensive support to families holding vigil at the bedside, as they may perceive their loved one is “going crazy” and/or grieve the loss of the person they knew and loved before death arrives. Inadequate control of agitated symptoms can contribute to posttraumatic stress, anxiety, and depression in family members as well as the staff who witness these difficult deaths \[32\].

First-line treatment of symptoms should always be nonpharmacologic measures, including increasing supervision and companionship at the bedside; minimizing use of physical restraints; minimizing the number of invasive lines and catheters, as able; padding the bedrails and lowering the bed, as able; maximizing uninterrupted times for sleep at night; and ensuring the patient has access to glasses and hearing aids.

For the pharmacologic treatment of delirium, antipsychotics are the drugs of choice; however, there is no high-quality evidence for their use, and there are no FDA-approved medications for delirium \[42\]. One expert guideline in 2013 outlined a rapid and safe titration strategy for antipsychotics on the basis of their pharmacokinetics—much in the same way that opioids are titrated for a pain crisis \[34\]. For example, a sample order could read “haloperidol 1 mg IV q15 minutes PRN for agitated delirium; call provider if no improvement after three doses.” This order is based on haloperidol’s time to maximum concentration in the serum (15 minutes). The provider can then schedule the patient’s total dose used in 24 hours in once-daily doses (not to exceed 100 mg per day) and continue the “as needed” doses that were previously effective for breakthrough agitation. For severe agitated delirium, chlorpromazine may be useful for its sedating, antihistamine properties as compared with haloperidol, which has stronger dopamine antagonism. Although benzodiazepines are generally avoided for treatment of delirium (and may cause delirium themselves), they can be effective for patients with a history of anxiety, alcohol use, previous benzodiazepine use, muscle spasm, and/or seizure risk \[34\].

For refractory agitated delirium of patients close to death, the ICU team can consider palliative sedation (PS) \[32\]. It is important to
understand the differences in intent between aggressive symptom management of delirium and PS. PS is the intentional lowering of awareness toward, and including, unconsciousness for patients with severe and refractory symptoms, as defined by the American Academy of Hospice and Palliative Medicine. PS is reserved for extreme situations and should only be used after all available options have been exhausted to treat refractory symptoms (for full discussion on palliative sedation, see Chapter 34) [43].

**Anxiety and Depression**

Patients with serious illness confront daunting psychological challenges and emotional upheaval. In end-of-life situations, patients face what Byock calls “the last developmental stage of life,” with opportunities for personal growth and enrichment of relationships [44]. This end-of-life work is difficult if physical and psychological symptoms, among other components of suffering, are not well managed. Although worry, sadness, and fear are normal responses to serious illness, ICU clinicians should be skilled in recognizing abnormal responses to stress, including anxiety disorders and depression. (For a comprehensive review of anxiety and depression, see Chapters 158 and 159 on Management of Anxiety and Depression.)

In one large study, nearly 50% of patients with advanced cancer met criteria for a psychiatric disorder, and among these patients, 68% had adjustment disorders with depressed or anxious mood, 13% had major depression, and 9% had organic mental disorders (delirium) [45]. Patients’ psychological health fluctuates over the course of terminal illness, and so regular reassessment and treatment of symptoms is crucial. In general, clinicians should be mindful of their own biases (“Of course she’s depressed—she’s got metastatic cancer”) that may impact their clinical judgment and ability to identify useful treatments and inadvertently convey a message of “giving up” on the patient.

**Anxiety**

It is common for patients to express anxiety and fear about the dying process and death. About 25% of patients with advanced illness suffer from debilitating anxiety symptoms and require treatment [46]. The ICU clinician should start with empathetically exploring a patient’s anxiety (“can you tell me what you are worried about or afraid of?”). An effective strategy is to listen, acknowledge the patient’s worries, provide empathetic support, and offer reassurance of ongoing care. If patients have persistently high levels of anxiety despite supportive-expressive therapy, a selective serotonin reuptake inhibitor (SSRI) and/or a low-dose benzodiazepine may be helpful (see Chapter 158 on Anxiety...
Management for specific medications and dosages). Mind–body treatments (e.g., meditation, cognitive-behavioral therapy, relaxation training) can be effective, especially when taught by a clinician trained in their use [47]. The ICU team should also diagnose and treat any contributors to a patient’s anxiety, including poorly treated pain or dyspnea, unrecognized delirium, substance abuse (intoxication or withdrawal), or medication side effects (such as corticosteroids).

**Depression**

Depression is normal for patients with life-threatening illness, and it can be overlooked and thus untreated [45]. It is common for dying patients to experience poor appetite and energy, changes in sleep patterns, and difficulty with concentration; feelings of hopelessness, helplessness, worthlessness, and pervasive guilt are markers of depression in this population. Depression interferes with the patients’ enjoyment of life, sense of purpose, and relationships with others. In addition, it can worsen pain and other physical symptoms and is associated with requests for hastened death. Risk factors include a previous history of depression, younger age, poor social supports, poor functional status, and pain [46]. In addition, certain medical conditions (hypo- or hyperthyroidism, anemia, and brain tumors) and medications (corticosteroids, interferon, tamoxifen, and other chemotherapeutic agents) can predispose patients to depression.

The single question, “Do you feel you are depressed?”, is useful as a screening tool [48]. Among patients with end-stage disease, the ICU clinician must differentiate major depression from grief. People who are grieving experience waves of sadness related to loss (or anticipated loss), but retain the ability to feel joy and pleasure. They may have passive thoughts and desire for death at times, but continue to look forward to the future. Meanwhile, depressed patients have unrelenting, intense, persistent anhedonia; have no hope or optimism for the future; and may have active suicidal thoughts.

Depression is a treatable condition, even for patients with end-stage illness. Although no controlled clinical trials have evaluated the efficacy of combined interventions in this population, many experts recommend a combination of supportive psychotherapy, patient and family education, and antidepressants. (See Chapter 159 on Management of Depression for specific medications and dosing.) In particular, psychostimulants act rapidly, counteract opioid-induced sedation, and have analgesic activity.
They can be the treatment of choice in patients facing a short prognosis, and they are often combined with an SSRI in severe depression (and while the SSRI is taking effect over weeks to a month). Serotonin-norepinephrine reuptake inhibitors can be good choices for patients with both depression and neuropathic pain, whereas the antidepressant mirtazapine also can improve appetite, anxiety, nausea, and insomnia at low doses.

The ICU team should consult specialists in palliative care and/or psychiatry for patients with refractory depression and anxiety, unusually intense grief, and/or persistent requests for hastened death.

**Last Hours of Living and Syndrome of Imminent Death**

ICU clinicians frequently witness patients dying of critical and chronic illness. These deaths can be sudden and unpredictable, or expected after a long decline; exhaustive after a lengthy medical “fight” to save or prolong a patient’s life; calm with recognition and planning for end of life, or some combination of all of the above. Regardless of the path, the ways that patients die have profound ripple effects on families, loved ones, and ICU staff for years to come. It is paramount for ICU clinicians to have the knowledge and skills to expertly care for dying patients, and cultivate a calm, empathetic presence to counsel and reassure grieving families at the bedside [49].

**Preparing for the Last Hours of Life**

The ICU team should anticipate that actively dying patients require continuous skilled care and attempt to create an environment in the patient’s room that supports privacy and intimacy. The patient and family should be reassessed regularly, and staff should be able to respond quickly to symptom crises and/or family concerns. Standardized order sets can help promote best practices, and utilization of the entire interdisciplinary team (including social work and chaplaincy) can address all aspects of suffering (see Fig. 35.1). If staff and family members feel confident in their caregiving abilities, the experience can be a meaningful time of life review, legacy creation, celebration, and healing. While the timing of death can be unpredictable, everyone should be aware of the potential time course, signs of the dying process, and how to manage any symptoms. The ICU team should also inquire about faith and cultural traditions (including after-death care and handling of the patient’s body) and strive to honor any requests and rituals.

**Physiological Changes and Symptoms**
In order to effectively manage symptoms and counsel families, ICU clinicians need to understand the pathophysiology of the dying process and common associated issues\textsuperscript{[49]} (see Fig. 35.1).

**Medication use.** As patients approach death, their absorption, metabolism, and excretion of drugs is highly impaired; therefore, clinicians should reassess the need for each medication and minimize polypharmacy and potential side effects as much as possible. Choosing the least invasive route of administration, medication should be used for relief of pain, dyspnea, excess secretions, agitated delirium, and seizure prophylaxis, depending on the clinical scenario. Patients should never be started routinely on morphine infusions (“start 1 mg per hour IV, titrate to comfort”) in the absence of symptoms. Sound pharmacologic principles always apply, such as the use of morphine IV boluses as needed for intermittent pain, and calculation of basal infusions on the basis of the amount of as-needed dosing. Indiscriminate morphine dosing can lead to build-up of active metabolites\textsuperscript{[4]} as renal failure occurs, resulting in agitated delirium from opioid neurotoxicity and/or hastened death (Fig. 35.1).

**Fatigue and weakness.** As a patient approaches death, providing sufficient cushioning on the bed will decrease the need for frequent turning and repositioning. Patients may have joint position fatigue and require passive range of motion of their joints every few hours.

**Decreasing appetite, thirst, and intake.** Families often worry that their loved one is “starving” and feel guilt that they are causing or contributing to death. Most patients lose their appetite and thirst, instead preferring bites and sips of favorite foods and fluids, and in the final hours prefer only mouth care. Studies show that parenteral or enteral feeding patients close to death neither prolongs life nor improves symptom control\textsuperscript{[50]}. Instead, indiscriminate use of artificial nutrition and hydration can lead to anasarca, pulmonary edema, upper airway secretions, and increased incontinence, contributing to skin breakdown. Most experts agree that anorexia and dehydration as part of the dying process may be helpful as the resulting ketosis and endorphin release can promote a sense of well-being\textsuperscript{[51]}.

**Mucosal and conjunctival care.** Meticulous hydration of the lips, nose, and eyes can prevent discomfort from dry, cracked, and irritated mucous membranes. Moisten and clean the oral mucosa frequently, and treat oral candidiasis with topical nystatin. Coat the lips and anterior nasal mucosa with a thin layer of lubricant to reduce evaporation (which should be nonpetroleum based if patient is using oxygen). If eyelids do
not close, moisten conjunctiva with artificial tears or ophthalmic lubricating gel frequently.

**Cardiac dysfunction and renal failure.** Dying patients have diminishing peripheral blood perfusion, and families will notice mottling of their loved one’s skin (livedo reticularis). Tachycardia, hypotension, peripheral cooling, and peripheral and central cyanosis are expected. Urine output drops as renal perfusion decreases, and eventually oliguria or anuria occurs.

**Neurologic dysfunction.** The neurologic changes associated with the dying process often follow two different patterns [49]—the “usual road” and the “difficult road” (see Fig. 35.1). Most patients follow the “usual road,” which leads to decreasing levels of consciousness, coma, and death. In the “difficult road,” patients experience increasing levels of confusion, restlessness, and agitated delirium (see management of delirium in this chapter). Despite patients’ decreased abilities to communicate, families and clinicians should talk to the patient as if she or he were conscious because data from the operating room and “near death” experiences suggest patients may be more aware than caregivers perceive. Families and friends should also be encouraged to express their feelings to the patient to help with life closure (“I love you,” “I forgive you,” “Please forgive me,” “Thank you,” and “Goodbye”) [52].

**Respiratory dysfunction.** As patients are close to death, their breathing patterns become shallow and rapid with periods of apnea (Cheyne–Stokes respirations), followed by agonal breaths in the moments before death. Families and clinicians often find these patterns distressing, and it is important to counsel them on these expected physiologic changes. If patients appear to have increased work of breathing (evidenced by accessory muscle use and grimacing), low doses of opioids can help reduce the perception of breathlessness [39].

**Loss of ability to swallow.** During the dying process, patients eventually use the ability to swallow due to weakness, impaired cognition, loss of gag reflex, and reflexive clearing of the oropharynx. As a result, oral secretions accumulate and may lead to gurgling or rattling sounds with each breath, which can be distressing to families. Repositioning and postural drainage can often resolve these sounds; if not, anticholinergic medications can be effective in drying these secretions. Glycopyrralate is the drug of choice because it does not cross the blood–brain barrier.
compared with other commonly used anticholinergic agents (atropine and scopolamine) and is likely less to induce or worsen delirium.

**When death occurs.** Even when death is expected, no one knows what it will feel like until it occurs. The interdisciplinary team is essential to supporting families in their acute grief, and following up on those with complicated grief. After a death, the ICU team should disconnect any lines or machines, remove catheters, and clean the patient to help create a peaceful vision of their loved one. Families should not feel rushed and encouraged to touch and hold the person’s body (while maintaining universal body fluid precautions). The ICU team should take time to debrief their own sadness and distress, especially in challenging cases. Equally important is acknowledging the sense of satisfaction and meaning that comes with helping a patient die in comfort and dignity and supporting a family through this devastating time in their lives (see Chapter 36).
REFERENCES

INTRODUCTION

With modern medicine has come the ability to prolong the course of illnesses that previously caused rapid decline and death. Critical and life-threatening illness often brings existential and spiritual concerns to the fore. One consequence of our ability to delay death with modern medical treatments is the prolongation of existential suffering as patients cope with the knowledge that death is imminent. While clinicians may feel competent and knowledgeable in addressing physical symptoms and psychological distress, existential and spiritual concerns can be more intangible, complex, and challenging, falling outside of what most physicians consider to be their scope of practice [1].

Some data suggest that existential and spiritual concerns may cause more distress to patients than physical and psychological symptoms [2]. Despite this, a majority of patients do not feel that their spiritual needs are supported by medical providers [3]. Barriers identified by physicians include a lack of time, lack of experience, and the belief that addressing spiritual distress is not part of a physician’s role [1]. Patients who feel that their spiritual needs are not addressed adequately by medical providers rate their care more poorly [4]. In contrast, patients and families who are satisfied with how their spiritual needs are met (and those for whom clergy have been involved at the end of life) are more satisfied overall with their care [5].
Starting a dialog about spiritual and existential concerns opens the door to a holistic model of care and healing. By developing an understanding of the types of existential and spiritual distress from which patients and their families can suffer, as well as specific approaches toward addressing this distress, clinicians can enhance their ability to provide compassionate and holistic care for patients at the end of life as well as their loved ones.
DEFINITIONS

Suffering was defined by Cassell [6] in his seminal work as “the state of severe distress associated with events that threaten the intactness of the person”. Existential distress can be difficult to define—one review identified 56 different definitions in the literature [7]. In addition, there can be substantial overlap between the concepts of existential and spiritual distress. Kissane [8], building on the work of Yalom, describes eight main types of existential challenge: death anxiety, loss and change, freedom with choice or loss of control, dignity of the self, fundamental aloneness, altered quality of relationships, search for meaning, and mystery about what seems unknowable. Loss of control over one’s life, loss of meaning, or the experience of being a burden (which relates to dignity of the self) are common symptoms that patients describe as being “unbearable” [9].

There are many definitions of spirituality described in the literature, though most include an exploration of meaning, transcendence, and relationships with self, others, and force(s) larger than oneself. An international group of experts has defined spirituality in specific terms: “Spirituality is a dynamic and intrinsic aspect of humanity through which persons seek ultimate meaning, purpose, and transcendence, and experience relationship to self, family, others, community, society, nature, and the significant or sacred. Spirituality is expressed through beliefs, values, traditions, and practices” [10]. Spirituality can be a key means through which patients cope with illness and mortality.

Religion can be defined as a particular system of faith and worship [11], and as a formal structure through which beliefs are practiced within a community.
RELIGIOUS TRADITIONS AT THE END OF LIFE

Religion and spirituality can impact medical decisions that are made at the end of life, though many differences across patients attributed to religion and spirituality are more accurately ascribed to cultural beliefs and values [12]. There are large and meaningful differences between spiritual and religious groups and, even more so, within them. Different religious traditions have heterogeneous views on the definition of death and on the withdrawal of life-sustaining interventions.

With the development of biomedical technologies and the medicalization of end-of-life care, spiritual and religious leaders are being increasingly called upon to speak to the appropriateness of end-of-life treatments and decisions. Specific formalized doctrines and proscriptions within individual traditions will be summarized below. These beliefs can shape the decisions of individuals around treatment decisions, though providers are cautioned to practice using a model of cultural humility rather than cultural competence [13]. In other words, physicians should avoid making assumptions about the beliefs of an individual, which may be very different than those expressed by the religious institution with whom they identify.

Christianity

Most Christian denominations support the withholding and withdrawal of life-sustaining treatments, though there is heterogeneity among Protestant denominations on physician aid in dying. The Greek Orthodox Church, in contrast, generally opposes the withholding and withdrawal of life-sustaining treatments and artificial nutrition, even for patients who wish to forego these treatments, maintaining in a statement from the Holy Synod that “the doctor has the moral obligation to assist the patient to consent to the effort being made to keep him alive” [14].

Catholicism

The Roman Catholic Church allows for the withholding and withdrawing of life-sustaining treatments if those treatments are deemed to be futile, burdensome, or disproportionate to the expected outcome. If treatment is deemed as such, the Church also supports the alleviation of suffering, even when consciousness is reduced and death hastened as unintentional side effects. However, the Church does not find it ethical to withhold or
withdraw treatment based on patient’s wishes if active treatment would be considered reasonable and life-prolonging [12,15].

**Judaism**

Jewish law (Halakha) dictates that death cannot be hastened, even when illness is terminal. A clear distinction is made between active and passive actions and between withdrawing and withholding life-sustaining interventions. Neither physician aid with dying nor withdrawal of continuous life-sustaining treatments that have already been initiated is allowed. Allowances can be made to first switch continuous treatments (such as mechanical ventilation) to intermittent settings (e.g., putting ventilators on timers), then discontinuing these treatments, given that continuing these interventions may cause suffering, the alleviation of which is a moral requirement [16]. Withholding life-prolonging treatments is considered permissible [12].

**Islam**

Islamic law (Shariah) dictates that all efforts should be made to prevent premature death, though withholding and withdrawing treatments at the end of life are permitted, provided that death is inevitable and that treatments are unlikely to improve outcomes or quality of life [12].

**Hinduism and Buddhism**

Buddhist and Hindu traditions share the belief that the body and the soul exist separately and that the body can be shed as the soul lives on or is reincarnated. In both traditions, it is believed that the time of physical death (e.g., death pronouncement) is only the beginning of the process of death for the soul [17]. Hinduism has many diverse interpretations and encompasses a myriad of traditions, though a “good death,” late in life, peaceful, with one’s affairs in order, is valued. The belief that this current life is a transition between the one before and the one after shapes views around end-of-life care and priorities [18].

**Atheism**

Little data exist describing the end-of-life preferences of patients who identify as atheist or agnostic. However, one small study found that atheists may have a conceptualization of a “good death” similar to other
patients, but may have stronger preferences for evidence-based medical treatments at the end of life and physician aid when dying [19].
IMPACT OF RELIGIOSITY ON END-OF-LIFE DECISIONS

The literature evaluating the effect of religiosity on end-of-life care preferences is mixed. Some data suggest that other factors may have a bigger impact on resuscitation preferences than religiosity [20,21]. Other studies have demonstrated that patients and families who identify as religious or spiritual [3,22], who utilize spiritual coping strategies [23], and who express deference to God’s will [24] are more likely to choose treatments to extend life. Patients who identify as religious may also be less likely to opt for a do-not-attempt-resuscitation order [25]. Additionally, those who feel that the length of life is determined by a higher power are less likely to engage in advance care planning [26].
Existential suffering is poorly understood by many clinicians [7], which can make it difficult to recognize and treat. Because suffering is experienced by the whole person, and not limited to a specific part of the body or mind [27], developing an understanding of personhood is key to identifying and addressing suffering. Some existential distress is related to physical suffering and loss of dignity and personhood as patients struggle with life-limiting illness [28], and, conversely, loss of dignity and personhood is associated with an increase of physical, psychological [29], or existential suffering [30]. Personhood also has many definitions, though common themes include that persons are unique and rational, possessing of autonomy, intention, and purpose [31]. The notions of personhood and person-centered care are central to the provision of competent and holistic palliative and end-of-life care. Cassell highlights the wholeness of personhood, writing that “the understanding of the place of person during human illness requires a rejection of the historical dualism of mind and body” [6].

The Patient Dignity Question (PDQ) has been proposed by Harvey Chochinov and colleagues [32] as a means to evaluate personhood and is simple and straightforward to ask: “What do I need to know about you as a person to give you the best care possible?” Epstein and Back [33] have offered the question “What’s the worst part of this for you?” as a means to recognize suffering, cultivate curiosity and empathy, and engage with patients in a deeper way—what they term “turning towards suffering”.

Additionally, the Pictorial Representation of Illness and Self Measure (PRISM) tool was developed to aid with the assessment of suffering and the impact of illness and has been used specifically to assess spiritual and existential distress [34]. The PRISM tool consists of a white board and a fixed yellow circle representing the self. A smaller red circle represents their disease process, and patients are asked, “Where would you put the illness disk to represent its place in your life right now?” The distance between the middle of the self and the disease disk is termed the self–illness separation. This correlates inversely with suffering and positively with perceived control over illness and coping resources.

The Faith, Importance, Community, and Address (FICA) tool [35] is a useful guide to begin conversations between providers and patients about spirituality. The questions include:

- Faith, belief, and meaning
Importance and influence
Community
Address/action in care

This tool can allow providers to open the door to further exploration and discussion around spiritual and existential distress and coping mechanisms. Another acronym, HOPE, provides a similarly useful framework for spiritual assessment [36]:

H—sources of hope, meaning, connection, strength
O—organized religion
P—personal spirituality and practices
E—effects on health care and end-of-life decision-making

Table 36.1 summarizes useful tools for spiritual assessment and sample questions.

| | “Are there any ways in which you could imagine your religious beliefs coming into conflict with the care we are providing?” |
| | “Would you like for us to have our hospital chaplain explore this in more detail with you?” |
| | “How can we address these aspects of your care while you’re in the hospital?” |
ADDRESSING EXISTENTIAL AND SPIRITUAL DISTRESS: USE OF AN INTERDISCIPLINARY TEAM

The need to integrate the assessment and treatment of existential and spiritual distress is important for the care of the critically ill patient. This is particularly important given the acknowledgment, as outlined before, that increased sense of religiosity may impact preferences related to end-of-life care, and the fact that addressing spiritual and existential suffering improves quality of life even at the end of life [1]. Critical and palliative care teams commonly utilize an interdisciplinary approach involving psychologists and social workers to help address the emotional distress of patients. A similar model of interdisciplinary collaboration is needed to most effectively—and efficiently—meet the needs of our patients who experience spiritual suffering [37] (Fig. 36.1).

FIGURE 36.1 Interdisciplinary care of the critically ill patient.
The hospital specialist in the spiritual domain is the chaplain. Within this specialty, there are two principal types of chaplains. This distinction should be recognized by clinicians to understand the nature of the relationship between patient and chaplain before hospitalization as well as the chaplain’s familiarity with serious illness and the health care system:

1. The hospital or health-system–based chaplain (health care chaplain) is most often employed by the hospital. This type of chaplain serves the spiritual and religious needs of patients regardless of faith. They are often called to support patients and families whether or not they self-identify as religious or spiritual. The health care chaplain usually has a master’s degree, and formal certification requires at least an additional 1,600 hours of training in clinical pastoral education or CPE. Just as with physicians, there is a tacit agreement to abide by a specific code of ethics and professional practice standards. These chaplains work closely with clinical teams, are integrated with the spiritual and faith communities of the patients they serve, and often collaborate with denominational chaplains (see the following paragraph).

2. The denominational chaplain is usually employed by a specific faith-based group, providing outreach to members of their religious community. These chaplains are not mandated to have the formal clinical training of their health care–based colleagues and can have a widely variable level of familiarity with critical illness and supporting those in medical crisis [38].

BOX 36.1: CASE EXAMPLE

Addressing Spiritual Needs in the Intensive Care Unit

Ms. M is a 20 year-old young woman in a motor vehicle crash who sustained a severe traumatic brain injury and multiple fractures. Her hospital course has been complicated by multi-organ system failure. Due to the extent and nature of her injuries, the neurology consult service has communicated to the family that they do not think she will have any meaningful neurologic recovery, though she is not brain dead.

Her parents and two siblings have been involved in multiple family conferences over the course of her hospitalization. They identify as evangelical Christians and have been well supported by their church community during this time. They express a wish to continue life-
sustaining treatments including mechanical intubation, and pressors indefinitely, stating that they have been praying for a miracle, and that Ms. M needs to be kept alive long enough to allow that miracle to occur.

The ICU team consulted both the hospital chaplain/spiritual care service, and the palliative care team. The chaplain first met with the family separately as well to explore their theology and their conceptualization of how a miracle might occur. Through these conversations, they came to feel that God would intervene with a miracle if He chose, independent of the artificial means of life support that were being provided by the medical team. They also felt strongly after these conversations that God would not want Ms. M to suffer. Over a series of family conferences that all began with prayer, the family agreed to make the patient DNAR, and later agreed to withdraw ventilator support and pressors.

While the physician, nurse and social worker can assess and provide basic spiritual support for critically ill patients and their families, collaboration with chaplains, especially health care chaplains, is considered a best practice to address the spiritual needs of both patients and families [39].

Furthermore, as previously mentioned, data suggest that family members of patients who died in the intensive care unit (ICU) rate the overall experience better when chaplains were involved in the care of their critically ill loved ones during the final days of life [4]. Too often, chaplains are called in to see patients only in the final hours of their lives. Offering chaplaincy support to patients and families of critically ill patients earlier in their hospital stay may help address patient and family anxiety (see Box 36.1 for case example).
HOPE AND RESILIENCY—RESTORATION OF PERSONHOOD

Hopefulness is not merely an emotion, nor is it considered by psychologists to be something that is passively received. Rather, hope is a dynamic cognitive construct—both an emotion and a behavior. Hope not only has a role in life when looking forward to a bright or ambitious future, but also plays a critical role for helping people cope with and reframe serious life events, such as trauma, illness, and even death [40].

Redirection of what to hope for and supporting a means of hope may strengthen patient–clinician bonds and prevent feelings of abandonment [36]. When fighting a life-threatening illness, maintaining hope can help patients and families foster emotional resilience. Clinicians often hesitate to share prognostic information with patients and family members for fear of depriving them of hope. Research indicates that physicians avoid prognostication for fear of (1) causing anxiety and increased stress for patients and families, perhaps worsening their clinical outcomes; (2) influencing colleagues’ attitudes about their effectiveness of care, potentially decreasing vigilance in the fight to cure; and (3) naming a possible negative outcome could make it more possible [41,42].

In contrast, many patients and families report that honest discussion about prognosis does not interfere with hope, and perhaps even helps support its maintenance. Despite this preference, family members of critically ill patients often demonstrate avoidant behaviors that suggest not wishing to “know all.” This demonstrated ambivalence reflects the emotional struggle of not wanting to acknowledge their loved ones’ serious prognosis. This difficulty can be mitigated by frequent clinician conversations to help patients and surrogate decision-makers process and prepare for the worst, while continuing to hold on to hope for the best realistically possible outcome [43,44] (e.g., “hope for the best, and prepare for the worst”).

Furthermore, similar to suffering, a patient’s individual notion of what hope is should be explored. Often, while the initial reflexive response is to survive or to return to good health, when examined further, the answers are more complex. Physicians often believe that when patients and their families ask whether something more can be done, they are referring to whether another procedure or intervention is possible. However, patients are often asking whether more can be done to help restore their personhood—some improvement in their physical well-being, an increased ability to return to performing in their identified roles, or
simply to return home without suffering. They are also often asking for clarity in prognosis and support for themselves and their families to complete their life story with respect for the way they have always lived [45].

Life review and dignity therapy are psychotherapy methods specifically for patients with life-limiting illness. These approaches seek to support the dignity and resiliency of the person. Dignity therapy was developed by Dr. Harvey Chochinov to address sources of psychosocial and existential distress as well as provide a means of recording in a written legacy or “generativity document” thoughts they find valuable for their loved ones. The interview technique focuses on the events, roles, and accomplishments that were most important to the patient over their lifetime and also allows the dying person to share their hopes and dreams for those they will leave behind [46]. The meaning making that is created through dignity therapy has been shown to decrease patient suffering and increase a sense of both dignity and purpose [47].
IMPACT OF MEDICAL DECISIONS ON GRIEF AND BEREAVEMENT

Grief is a normal response to the loss of a family member or close friend. This can be a consequence not only of death itself, but also the loss of what constitutes the “personhood” of someone loved. For example, after 55 years of marriage, a wife can grieve the loss of her independent spouse who now needs to be placed in nursing home after a traumatic fall. A young athlete can grieve the loss of his sense of future and identity after having suffered a spinal cord injury. Grief also does not only occur after trauma, but also with protracted illness, or other intense loss.

Most people exhibit tremendous resiliency when grieving the death of a person loved. Resiliency can come from connection with sense of purpose, reflection on meaning of the relationship and life review, and both spiritual and religious factors. Respecting and infusing religious traditions and values at the end of life can further help add meaning to the loss. In many religions, ensuring a patient’s honor and integrity at the end of life can support a family’s bereavement. In Islamic tradition, for example, these efforts can reflect a family’s acceptance of the Koranic teaching that there are times to let nature take its course (Al-Qur’an 39:42) and an assurance that their advocacy role as loving family members has been fulfilled [48].

However, approximately 10% of people who grieve develop protracted symptoms, what used to be called complicated grief disorder, but now is characterized as either depression or adjustment disorder of DSM-5 [49]. Historically, a “bereavement exclusion” was made in the diagnosis of major depressive disorder—reflecting a belief that bereavement is a natural process and should not be pathologized. While it shares some symptomatology with major depression, grief has unique features as well, including the preservation of self-esteem, and positive memories and feelings related to the loved one combined with sadness. The bereavement exclusion was removed from DSM-5 [49], though differentiating between major depression and grief remains complex [50].

Social isolation and underdeveloped coping mechanisms contribute to the risk of complex grief [51]. Perceived conflict between medical decisions and religious beliefs may contribute to increased suffering
During bereavement [52,53]. In particular, this may be due to beliefs that the deceased may suffer consequences of decisions made during the final weeks of life. For example, in Buddhism, some believe that terminal delirium or confusion may cause the soul to become lost during the process of rebirth. It can be helpful for the medical team to seek guidance not only from the ethics committee, but also from religious leaders and experts to help inform how specific religious medical ethics and laws could influence decision-making. When appropriate, and with the help of chaplaincy, reassuring families that their decisions are consistent with their religious beliefs (especially around topics such as withholding or withdrawing life support, nutrition, or other interventions) can help mitigate grief responses that come out of spiritual distress or conflict.
SELF-CARE AND AVOIDING BURNOUT

Spirituality, as defined in this chapter, is broader than religion and religiosity. It is about resilience, hope, meaning making and purpose, and the ability to tend to suffering. As such, it is a concept that does not only apply to something assessed and offered to patients. Rather, in this broader sense, it can play a central role for preventing burnout among critical care physicians and nurses. Studies suggest that up to 50% of ICU physicians and 30% of ICU nurses meet criteria for severe burnout [54].

While for many, burnout is associated with long work hours and increased productivity pressures, for others, burnout is more causally related to end-of-life care conflicts, such as moral distress associated with poor interprofessional and provider–patient/family communication around end-of-life care issues [55]. Furthermore, burnout is linked with an individuals’ level of motivation for excellence in their work and willingness to put aside self-awareness and self-care. Major characteristics of burnout include emotional (and physical) exhaustion, depersonalization, and a diminished sense of professional accomplishment or effectiveness. Physicians often correlate patient outcomes with their sense of personal effectiveness. In other words, for many, death of a patient—regardless of cause—equates with clinical failure. This makes care of patients at the end of life particularly high risk for clinician burnout. Unfortunately, research is demonstrating that patient outcomes may also be affected by clinician burnout [56].

In this way, the death of patients in the ICU adds not only to the emotional labor of the work, but also to the risk of burnout among clinicians.

Factors that help mitigate or prevent burnout include not only intrinsic personality characteristics such as hardiness, but also workplace factors such as perceived fairness and sense of support and control. Active spiritual practices such as mindfulness meditation, reflective writing, and cultivation of self-awareness have also demonstrated utility. The interdisciplinary team can play a role for supporting patient care providers’ resiliency. Sharing the challenging experiences of caring for people with one’s colleagues lends mutual support and counteracts the risk of burnout [57].
SUMMARY

In summary, spiritual and existential concerns are often at the forefront at the end of life (Table 36.2). Many physicians feel ill-equipped to address these issues, but engaging with patients around spiritual and existential distress is an essential part of holistic care. Religious theology and religiosity in general may influence decisions made at the end of life, though there is significant variability within religious and cultural traditions. Tools exist to help physicians assess spirituality and religiosity, as well as personhood and overall suffering. Interdisciplinary collaboration, particularly with chaplaincy, is critical in ensuring that the spiritual and existential needs of the person/patient have been fully addressed. Clinicians have an obligation to be truthful with patients and families about prognosis and also to help foster hope as a tool to build resiliency through critical illness. Finally, clinicians who care for patients at the end of life and in the ICU are at high risk for burnout and are well served to use tools such as meditation and reflection, as well as the support of an interdisciplinary team to maintain their own personal wellness.

INTRODUCTION

Early recognition of exsanguinating hemorrhage is critical to the survivability of an acutely bleeding patient. Typical methods of in-hospital assessment, including blood pressure and hemoglobin levels, are often misleading, and reliance upon these methods frequently result in late recognition of hemorrhagic shock, giving rise to higher mortality rates. Advanced Trauma Life Support program teaches health care providers to incorporate basic physical examination skills (vital signs, pulse pressure, skin color, capillary refill, and mentation) to stratify injury severity, identify and treat immediate threats to life, and to quantify blood loss [1]. Rapid, focused assessment is necessary to expeditiously identify those patients who are either in hemorrhagic shock or at risk for developing it.

Surgical patients die from shock either abruptly via inadequate oxygen delivery or subacutely through development of multisystem organ dysfunction from late recognition or inadequate resuscitation. Unlike the typical nonsurgical critically ill patient, organ dysfunction is often resulted from the acute effects of exsanguination. Hemorrhage accounts for up to 40% of trauma deaths, second only to central nervous system injury [2–4]. Controlling hemorrhage is thus a priority for modern trauma patient care; however, the source of hemorrhage must first be identified, and identified early.

Prior to, during, and following surgical intervention, ongoing resuscitative efforts must proceed appropriately to avoid the sequelae of hypoperfusion. Although commonly utilized in nonbleeding patients,
intravenous (IV) crystalloid infusion may only provide temporary volume repletion. Additionally, crystalloids increase acidosis, can contribute to coagulopathy, cause immunologic dysfunction, and impose pulmonary and renal risks, and, therefore, have limited use in the hemorrhaging patient [5]. Lost cellular components, coagulation factors, and oxygen-carrying capacity require directed replacement to achieve normal perfusion.

Trauma-induced and consumptive coagulopathy presents a unique challenge not present in other shock states. In addition to the quantitative loss of essential clotting components, hemorrhage results in hemostatic functional failure. Hyperfibrinolysis, progressive thrombocytopenia, acidosis, and hypothermia all contribute to worsening coagulopathy that mandates aggressive, early, and targeted management.

A variety of methods have been utilized to determine endpoints of resuscitation following significant hemorrhage. Failure to direct resuscitation to these specific goals may lead to over-or-under resuscitation and the multitude of deleterious effects of either. No single endpoint has proven adequate, further elucidating the importance of a keen understanding of the physiologic consequences of bleeding.

Following initial resuscitation, ongoing need for blood products and hemostatic adjuncts suggests the presence of a missed injury or ongoing surgical bleeding not yet controlled. Although not always clear, failing to recognize the need to return to the operating theatre or endoscopy or interventional suite will result in worsened physiology, often beyond recovery and repair.

The myriad of issues encompassing shock following hemorrhage require diligence, foresight, and intuition in order to orchestrate a successful resuscitative strategy, while minimizing the complications associated with the disease state, as well as complications of the resuscitation.
PHYSIOLOGIC RESPONSES TO HEMORRHAGE

Coagulopathy

Acute coagulopathy resulting from hemorrhage is not a new concept, but recent work has further elucidated causes and potential treatments for coagulation disturbances associated with acute, large-volume blood loss. When present, coagulopathy is associated with higher mortality, up to four times that of patients with normal coagulation profiles [6].

Dilutional coagulation dysfunction has long been at the forefront of arguments against the use of large-volume prehospital or in-hospital resuscitation with crystalloid volume. With continued hemorrhage, plasma constituents necessary for hemostasis are not repleted and diluted. Replacing only the lost volume with crystalloid not only fails to replenish plasma constituents but also dilutes those remaining coagulation elements, thereby worsening hemorrhage. Additionally, crystalloid dilutional resuscitation has also been linked with increased hyperfibrinolysis—a deadly combination. However, multiple studies have shown this to be only one component of coagulation disruption, because coagulopathy in the absence of crystalloid resuscitation remains a significant problem, most notably following injury [7].

Consumptive coagulopathy, originally thought to be the primary cause of clotting dysfunction seen in patients sustaining significant hemorrhage, is rooted in the concept of localized exhaustion of clotting factors, platelets, thrombin, and other hemostatic activators. In severe multisystem tissue damage, such as massive crush injury, this likely plays a key role in the basic view of hemorrhagic coagulation dysfunction. However, coagulopathy is often associated with major, single site hemorrhage where direct tissue damage is limited, such as intraoperative vascular injury or isolated organ trauma from a single gunshot wound, suggesting that systemic effects are at work [8].

Approximately 25% of traumatized patients will present with coagulopathy that differs from these classic interpretations of causative mechanisms [9]. Although dilutional and consumptive causes certainly play a role in the acute coagulopathy of hemorrhage, dysregulated systemic activation and deactivation of key hemostatic mediators, as well as hypoperfusion, significantly contribute to systemic hemostatic failure. This is evidenced by those patients who present with normal perfusion; and, despite massive tissue injury, the patients do not show signs of coagulopathy [10]. Direct tissue injury exposes tissue factor and type III
collagen within the subendothelium of damaged vessels. Binding of von Willebrand factor, platelets, and factor VIIa leads to thrombin and fibrin formation. This process is then amplified by factor IX, propagating initial hemostatic response to hemorrhage. Because hemostasis is part of a coagulation continuum, whereby clot formation and lysis are principal components, the release of hemostatic factors is accompanied by concomitant increases in lytic factors. Endothelial exposure from injury and thrombin formation also result in release of tissue plasminogen activator (tPA). Additionally, plasminogen activator inhibitor 1 (PAI-1) is inhibited, leading to increased plasticity of forming clots [8,11].

These local responses to tissue damage do not, however, fully elucidate the widespread clotting malfunction seen with large-volume hemorrhage. Systemic activation in response to hypoperfusion and shock has been implicated as a fundamentally necessary component of the acute coagulopathy of hemorrhage. This is seen with the thrombin–thrombomodulin–protein C complex. Hemorrhagic shock leads to increased circulating thrombomodulin, resulting in whole-body activation of protein C. Activated protein C then exudes its anticoagulant effects through degradation of clotting factors, specifically factors V and VIII. Studies have shown those patients in shock, regardless of degree of tissue injury, and have universally demonstrated deficiency in factor V [7]. PAI-1 is consumed, and thrombin generation subsequently downregulated on a systemic level as a result of increased protein C and glycocalyx shedding. The endothelial glycocalyx is a key regulator of vascular permeability, cell adhesion, and inflammation. At least one of four key components, syndecan-1, is shed during hemorrhagic shock exposing the membrane to inflammatory molecule adhesion, increasing permeability, and hyperfibrinolysis. The glycocalyx has been shown, at least in an animal model, to be replenished in plasma-based resuscitation and not with crystalloids [12,13].

The presence of shock is associated with hyperfibrinolysis and worsened outcomes. When percentage of lysis at 30 minutes (LY30), as defined by thromboelastography (TEG), exceeded 3%, the associated mortality risk increased 10-fold [6]. Although fibrinolysis is a normal physiologic process, hypoperfusion-related dysregulation of mediating factors results in overactivation of the fibrinolytic process. Plasminogen activators (tPA) cleave plasminogen to plasmin and are systemically upregulated in response to hemorrhagic shock. Additionally, the downregulatory activities of PAI-1 are inhibited through depletion [11]. This sets the stage for unrestricted lysis, diffuse hemorrhage, and
uncontrolled coagulopathy.

Often revered by clinicians as a key marker of a patient’s hemostatic ability, thrombocytopenia is associated with worsened outcomes. However, a normal platelet count does not ameliorate the risk of mortality related to functional platelet abnormalities, especially when considering that thrombocytopenia on admission is a rare event. In a study examining 101 severely injured trauma patients with normal platelet counts, over 40% demonstrated a defect in platelet function on admission to the emergency department [14]. Again, the presence of shock is to blame. Hypoperfusion leading to organ dysfunction, specifically hepatic perturbations, leads to the release of substances, causing calcium channel disruption and platelet inhibition [15]. Impaired fibrinogen–platelet interactions, decreased platelet responsiveness to arachidonic acid, adenosine diphosphate, and thrombin receptor-activating peptide as well as the classic inhibitors of hemostasis—acidosis and hypothermia—resulting from hypoperfusion also contribute to decreased platelet function [16].

Hemodynamic

Hemodynamic physiologic changes occur as a result of the need to ensure adequate tissue perfusion to vital organs. This is accomplished at the outset of severe hemorrhage through a multitude of cardiovascular mechanisms, led by sympathetic upregulation. Sympathetic outflow resulting from atrial and carotid body baroreceptors and loss of vagal tonic inhibition as a function of hypovolemia, causes cardiac chronotropic and inotropic responses. Epinephrine increases heart rate, which in turn maintains cardiac output, despite falling stroke volume. This is first recognized clinically by an increase in diastolic pressure, and consequent narrowed pulse pressure. With worsening hypovolemia, respiratory variations in pulse pressure may develop, worsening mean perfusion pressures significantly. Sympathetic activation also increases contractility through cardiac β-receptor stimulation.

Decreased arterial and venous compliance secondary to epinephrine release improves venous return in the face of hypovolemia. Peripheral vasoconstriction is clinically identified by the presence of cool extremities. Blood is shunted away from the periphery to vital organs, such as the heart and brain. Splanchnic perfusion is compromised because endogenous vasopressin and other sympathetic substances, such as endothelin and angiotensin II, stimulate vasoconstrictive receptor systems. Consequently, renal blood flow is decreased to only a fraction of normal levels, leading to acute kidney injury and oliguria. Celiac vasoconstriction decreases hepatic and portal flow, resulting in release of proinflammatory mediators, such as interleukin 6 (IL-6) [15,17].
On a microvascular level, increases in cellular adhesion molecules cause neutrophils to adhere to the endothelial cells in the microcirculation, limiting the physical ability of red cells to navigate capillary beds. Inflammatory mediators induce endothelial cell swelling, further limiting the passage of blood constituents. Decreases of capillary flow provoke cellular ischemia and anaerobic metabolism with ensuing acidosis [18].

As hypovolemia progresses, hemodynamic compensation fails. Cardiac output falls despite increases in contractility and heart rate. Vasoconstriction is maximized through exponential quantities of endogenous catecholamines; however, without volume, it is to no avail. Acidosis rapidly follows, heart rate variability declines, and bradycardia emerges signifying irreversible shock.

**Metabolic**

In 1872, Gross called shock a “rude unhinging of the machinery of life.” The machinery of cellular metabolism undergoes fundamental changes in the setting of hemorrhagic shock. Hypovolemic-induced depressions of cardiac output result in diminished perfusion to end organs. The remaining intravascular volume is deplete of hemoglobin mass, although concentrations may remain relatively stable in the initial phases. Limited hemoglobin mass correlates with decreasing levels of available oxygen. To counteract this, oxygen extraction increases, measured by declining mixed venous oxygen saturation, and the patient becomes dependent upon oxygen delivery to maintain aerobic metabolic pathways and stave off impending acidosis. As hemorrhage continues and the previously described hemodynamic changes occur, anaerobic metabolism begins to materialize. The resultant acidosis shifts the oxygen dissociation curve to the right, favoring oxygen offloading at the cellular level. Mild acidosis, therefore, executes a beneficial effect, curbing progressive anaerobic transformation temporarily. If hemorrhage control is not accomplished, the availability of cellular oxygen fades, and mitochondrial energy production is halted with accumulation of pyruvate. Reduction of the efficiency of the electron transport chain causes diversion of NADH that donates a proton to pyruvate with formation of lactate. Lactic acidosis then ensues until oxygen delivery restores the electron transport chain, at which time pyruvate may reenter the citric acid cycle and lactate production decreases.

Lactate clearance has been studied extensively as a marker of
resuscitation effectiveness based on these basic physiologic mechanisms. For lactate formation rates to normalize, orderly aerobic cellular metabolism must be restored. This is evidenced through an understanding of the Cori cycle, which begins with glycolysis. Yielding two adenosine triphosphates (ATPs), glycolysis also produces two lactates, which are then transported to the liver. Lactate is then converted back to glucose through hepatic gluconeogenesis at the cost of six ATPs, resulting in a net negative energy balance. Glucose then participates in glycolysis again at the cellular level, and the process repeats itself. This large energy gap cannot be replenished without resumption of normal physiologic metabolism, which requires restoration of oxygen delivery through hemorrhage control and resuscitative efforts. Therefore, normalization of lactate levels signifies success from a resuscitation viewpoint.

Blood glucose and glucose utilization is intimately linked to the production of lactate and energy. In response to hypovolemia and acidosis, adrenal medullary and cortical hormones are released. Cortisol not only aids in vasoconstriction but also promotes glucose release in large quantities to combat essential cellular starvation as a result of hypoperfusion. Insulin is suppressed, favoring glucose utilization as opposed to storage. Insulin-independent GLUT membrane proteins allow for transport of glucose to vital organs such as the heart, kidneys, brain, and others, and thus provide an increased energy source. However, lactic acidosis will continue in the absence of adequate oxygen delivery. Hyperglycemic deleterious effects are far reaching, and include increased infection and elevated intracranial pressure. Regarding direct correlation to hemorrhagic shock, however, hyperglycemia may result in osmotic diuresis despite decreased renal blood flow and glomerular filtration rate augmented by renin–angiotensin–aldosterone system activation, thereby worsening the already depleted intravascular volume. Growth hormone and glucagon add to this process because they promote lipolysis and glycogenolysis.

**Immunologic**

Hemorrhagic shock results in a multitude of immune responses related to the upregulation of cellular signaling designed to protect, but often result in harm. Extensive research in the last decade has shown that hemorrhagic shock activates inflammatory cascades, resulting in profound abnormalities. The effect of immunologic dysregulation is often manifested by a spectrum of clinical problems, including acute respiratory distress syndrome (ARDS), systemic inflammatory response syndrome (SIRS), coagulation abnormalities, and multiple organ dysfunction syndrome (MODS). Cytokines such as IL-1, IL-6, tumor
necrosis factor $\alpha$, cellular signaling pathways involving toll-like receptors, and microRNA have all been implicated [19]. However, there have been no clear data regarding which of the many involved substances plays the key role in development and propagation of the overactive inflammatory response. One of the major areas of study involves the activated immune response that results in enhanced activation and adhesion of leukocytes. During this activated stage, neutrophils can release harmful reactive oxygen species, which are thought to play a major role in loss of capillary integrity. This leads to edema and the sequestration of fluid in the tissues and the interstitial space. Additionally, immunologic responses to therapy, specifically large-volume crystalloid infusion, may trigger the altered immune response to hemorrhage and has been a growing area of research [20].
SHOCK RECOGNITION

Early recognition of hemorrhagic shock is essential to prevent mortality. Aside from blatant exsanguination, hemorrhagic shock can be difficult to define in its early stages. A high index of suspicion is necessary for prompt, accurate diagnosis. Probable mechanisms of hemorrhagic shock must be thoroughly and rapidly examined and treated.

Every patient who is at risk for hemorrhage should be evaluated through methods delineated in the Advanced Trauma Life Support program. By quickly proceeding through the primary survey (evaluation), immediate life threats are recognized and can be treated [1]. This presents a departure from traditional methods of initial patient evaluation of taking a long, thorough history from the patient, discussing options, and planning a workup. A hemorrhaging patient does not have the luxury of time, and delayed recognition of shock often results in death. Immediate threats to life must be identified early, and minor injuries or findings must not derail the primary goal of addressing potentially lethal matters.

No one feature results in the diagnosis of hemorrhagic shock. Basic physical examination skills utilized in context often form a clinical impression that leads to the diagnosis. Heart rate and blood pressure, which are often used in the incorrect definition of shock, may be normal. β-Blockers, untreated hypertension, and physical fitness may confound interpretation of hemodynamic normalcy. A narrowed pulse pressure, however, is typically present, and often missed owing to a normal systolic value. Anxiety or belligerence may be a sign of shock, and can easily be confused for intoxication or isolated brain injury. Decreased mental status should be considered an ominous sign of impending decompensation. Cool, clammy extremities in a patient at risk for shock are clinical markers for peripheral vasoconstrictive compensation. Pallor may also be present, and in an otherwise healthy patient, should invoke a sense of urgency. Hypothermia, a key component of the lethal triad (hypothermia, coagulopathy, and acidosis) is an independent predictor of mortality in hemorrhaging patients.

Exhaustive laboratory studies are often unhelpful, especially in the early stages of shock. For example, hemoglobin and hematocrit levels are frequently normal, because the laboratory result is a measure of concentration—which remains unchanged until compensatory mechanisms and interstitial to intravascular fluid shifts have occurred. However, when a hemoglobin of less than 11 g per dL is present, it is associated with a mortality rate of nearly 40% [21]. Most patients with hemorrhagic shock were physiologically normal prior to the offending
insult. This makes the arterial blood gas quite useful, because any acidbase abnormality can be presumed to be caused by the event that brought the patient to the hospital, and not underlying medical conditions. Patients with a base deficit (BD) greater than 6 are at higher risk of mortality and the need for massive transfusion. Severity of injury and mortality is linearly associated with the degree of the initial coagulopathy, and an international normalized ratio (INR) of greater than 1.5 reliably predicts the need for massive transfusion [10,22]. Tissue oxygen saturation continues to be investigated as a simple, reliable, and early marker of the presence of hemorrhagic shock [23].

Adjuncts to the clinical examination include very few imaging studies. For the injured patient, chest and pelvic radiographs may be of great utility because they can help identify major hemorrhage in two of the five key locations where deadly hemorrhage may occur. The Focused Assessment with Sonography for Trauma (FAST) may be utilized to identify tamponade, hemothorax, pneumothorax, and intraperitoneal hemorrhage. Long bone fractures are often readily identified. In nontrauma cases, a nasogastric tube may be inserted for suspected gastrointestinal hemorrhage to aid in localization. Endoscopy and interventional radiologic methods may also be employed emergently as conditions warrant.

Those patients who transiently respond to volume administration should undergo expeditious reevaluation to localize the cause of hemorrhage. Transient response conveys ongoing hemorrhage, and beseeches health care providers to act quickly to obtain hemorrhage control.

Shock scoring systems may aid in the clinical diagnosis of hemorrhagic shock when uncertainty exists. Many studies of hemorrhagic shock identification scoring systems use the necessity for transfusion as the outcome of interest. The Emergency Transfusion Score involves the use of nine markers, with a weighted coefficient assigned to each marker. For example, a systolic pressure of <90 mm Hg carries the most weight, at 2.5 times higher than mechanism of injury. The Trauma-Associated Severe Hemorrhage (TASH) system was developed in Germany and incorporates many of the clinical features described earlier, in addition to BD and hemoglobin. The TASH has been shown to reliably predict the need for massive transfusion [24]. A simplified method of identifying the probability of life-threatening hemorrhage was developed from military experience. Tachycardia, hypotension, acidosis, and acute anemia are all independent risk factors for the need of massive transfusion. When all
four are present, approximately 80% of patients will require massive transfusion. The validity of this model, however, rests on a weighted evaluation, with pH carrying the most value, and thus is difficult to rapidly calculate. [25]. The ABC score was developed to eliminate the need for laboratory results to rapidly determine the presence of hemorrhagic shock and to predict the need for massive transfusion. Four components (penetrating mechanism, systolic pressure < 90 mm Hg, heart rate > 120 beats per minute, and positive FAST), each with equal weight make up the ABC score. Patients with all four variables present have a near 100% need for massive transfusion [26].

Utility of Ultrasonography for Diagnosis of Hemorrhagic Shock

As discussed earlier, early control of the site of bleeding is an essential part of the management of hemorrhagic shock. Source control requires identification of the source of bleeding. Ultrasonography has utility for this purpose, because it can be deployed at the point of care for urgent evaluation of the critically ill patient. Ultrasonography has the advantage of immediate application by the frontline clinical team who can integrate the results of the examination into the other key elements of emergency evaluation: the history, physical examination, and initial laboratory results. This is not to discount the importance of advanced imaging techniques, such as computerized tomography (CT) or angiography; yet, these suffer the disadvantage of some inevitable delay in their performance.

The ultrasonography examination is performed by a member of the trauma team while other key elements of initial resuscitation are ongoing. Modern bedside ultrasonography machines are small enough that they can be brought to the bedside without blocking access to the patient by other members of the trauma team. The machine has multiple uses beyond examination for life-threatening hemorrhage, such as vascular access, airway management, and assessment for alternative causes for shock.

Examination for Intra-Abdominal Hemorrhage

The FAST examination utilizes ultrasonography to rapidly identify an intra-abdominal source of bleeding. It has replaced intra-abdominal lavage as the technique of choice for management of abdominal trauma and is standard practice for evaluation for intra-abdominal bleeding in trauma [39].
Scanning Technique

A phased array cardiac probe on abdominal preset gives serviceable images. If available, a curvilinear abdominal probe is used. The hepatorenal and splenorenal spaces are imaged in longitudinal axis to look for fluid collection. On the right side, the probe is placed in the midaxillary line on the lower chest wall in order to obtain a transcostal view of the liver in a coronal imaging plane (see Chapter 44 Critical Care of the Patient with Abdominal Trauma). Once the appropriate intercostal space is found, the probe is angled and tilted to achieve a clear image of the hepatorenal space. The presence of fluid is taken as an indication of intra-abdominal bleeding (Video 37.1). The examiner also checks for prehepatic fluid, and, using the liver as an acoustic window, examines the subdiaphragmatic space for fluid (Video 37.1). The scan is repeated on the left with examination of the splenorenal, presplenic, and subdiaphragmatic spaces (Video 37.1). The operator then checks for pelvic fluid. The probe is placed just above the level of the iliac crest in the midline using a transverse scanning plane and angling downward through the bladder to search for fluid in the pelvis (Video 37.1). Pelvic fluid indicates an intra-abdominal source of bleeding in the patient with hemorrhagic shock. Some examiners include examination of the right and left lower lateral abdominal quadrants to the FAST examination. The FAST examination may include the subxiphoid view of the heart (subcostal long-axis view) in order to exclude a hemoperidium with pericardial tamponade and to look for severe hypovolemia manifested with a small hyperdynamic left ventricle (Video 37.1). The subxiphoid view of the inferior vena cava (IVC) is included to examine for IVC size and respiratory variation. The presence of a small diameter IVC or respirophasic variation of IVC size suggests hypovolemia.

The FAST examination can be performed rapidly. If initially negative, it can be repeated as clinically indicated. In the presence of hemorrhagic shock, a positive examination indicates intra-abdominal bleeding and the need for urgent source control.

Examination for Hemothorax

The extended FAST examination uses elements of thoracic ultrasonography to evaluate the patient with hemorrhagic shock for hemothorax. In addition, the examination has utility to examine for pneumothorax and pericardial effusion on an emergency basis.

Scanning Technique

With the patient in supine position, fluid will distribute in the dependent
Examination for Retroperitoneal Bleed

Retroperitoneal bleeding is a potential cause of hemorrhagic shock that may be difficult to identify by physical examination. Ultrasound examination of the retroperitoneum is also limited, and has a high false negative rate. For this reason, in patients who present in hemorrhagic shock with no identifiable cause, a retroperitoneal source should be considered, and expedient operative intervention should proceed in instances where a high index of suspicion exists.

Scanning Technique

The probe is used to examine the flank area bilaterally. Using a coronal scanning plane, the probe is moved over the flank. Identification of retroperitoneal fluid collection indicates retroperitoneal bleeding and the urgent need for consideration of source control (Video 37.1).

Limitations of Ultrasonography

Ultrasonography readily identifies fluid collections. In hemorrhagic shock, the trauma team may reasonably assume that the fluid represents hemorrhage and takes action based upon this supposition. If the patient is unstable, this may result in early surgical intervention. If time permits, the finding may lead to further imaging with CT scan or angiography; if an interventional radiology approach seems appropriate.

Patient-specific characteristics such as obesity and edema may degrade the ultrasonography image. This is most likely to occur when imaging the retroperitoneum. Competence in scanning during emergency situations, such as for the evaluation of hemorrhagic shock, requires effective training for competence [40] because inaccurate results may have severe consequence in the unstable patient.

Perhaps the greatest limitation of using ultrasonography to identify
sources of hemorrhagic shock, is misinterpretation of a negative result. Patients who exhibit signs of hemodynamic compromise related to hemorrhage may have a completely normal ultrasound examination. When this occurs, providers should resist being lulled into complacency based upon the negative imaging examination, and must remain vigilant to ensure rapid hemorrhage control is obtained.

Despite these limitations, ultrasonography is an effective tool for the initial and ongoing evaluation of the patient with hemorrhagic shock. It can be fully integrated into the team effort at the bedside, and it gives immediate and valuable clinical information. As such, it is an essential component of the imaging strategy for the evaluation and management of hemorrhagic shock.
**HEMORRHAGE CONTROL**

Obvious external hemorrhage is controlled first by manual pressure. Pressure is the force applied per unit area. To effectively control hemorrhage with direct pressure, one must limit the area over which it is applied. For example, a finger placed deliberately is often more efficacious than two hands placed over a large surface.

Tourniquets have seen increasing use in both civilian and military populations in recent years. Commercially available tourniquets are simple to apply with minimal training, are lightweight, and effective at controlling extremity hemorrhage. Tourniquets should be utilized in manner in which they were designed, to occlude arterial hemorrhage. Isolated venous occlusion, without arterial cessation of hemorrhage, will worsen blood loss [27]. Junctional hemorrhage, occurring high in the groin, for example, is often difficult to control with pressure or tourniquets alone and, typically, requires emergent surgical intervention. However, adjuncts such as the junctional emergency tourniquet system may be useful for some patients [28].

Local hemostatic agents are widely available and have shown promise in controlling both external hemorrhage, and organ bleeding encountered in the operating suite. Topical hemostats are typically constructed of bioabsorbable material with the addition of thrombin and/or fibrin, and are available in a variety of application constructs. Polymerized sprays, injectable foam, and biologic sheets are among the many methods available. Cost and local availability often dictate which product may be utilized. It is important to avoid intravascular injection or placement of these products, because embolization is a risk.

Noncompressible torso hemorrhage has been identified as a major cause of death both in military and civilian studies [29]. Few techniques other than surgery are available to address noncompressible hemorrhage, such as bleeding in the abdomen, retroperitoneum, or chest. It is important to recognize that these techniques are temporizing measures in lieu of definitive hemorrhage control. Resuscitative thoracotomy, although effective for ceasing torso hemorrhage, is associated with high mortality rates, and is frequently impractical for the general physician to successfully accomplish. Resuscitative endovascular balloon occlusion of the aorta was first described over 50 years ago, and has seen increased use recently. It involves advancing and inflating an endovascular balloon into the aorta via percutaneous femoral artery access. This can be accomplished in the emergency department with minimal equipment and has been shown to be effective at controlling torso hemorrhage [30]. Self-expanding polyurethane foam, injected through percutaneous techniques
intraperitoneally, has shown promise and efficacy. The liquid polymer rapidly expands, conforming to intra-abdominal anatomy and stopping hemorrhage. The foam is then removed at the time of surgery. Studies are currently underway to further characterize this technique [31].

Surgical control of hemorrhage is beyond the scope of this chapter; however, it warrants mention. Once hemorrhagic shock is identified, immediate control of hemorrhage must be undertaken. Delaying definitive care with exhaustive radiologic or laboratory studies is unwise. At centers without surgical capabilities, rapid transport to a tertiary facility, when hemorrhage is suspected, is safer than definitively identifying the source of that hemorrhage. Control in the operating room or angiography suite is crucial to avoid death, and initial evaluation and management should effectively move toward that goal.

Systemic adjuncts for controlling hemorrhage in the presence of coagulopathy may be utilized to help normalize coagulation disturbances, and avoid ongoing bleeding. Many of these pharmacologic adjuncts are utilized off-label; however, significant data exists to support their use in certain situations. Prothrombin complex concentrates, initially developed to treat isolated congenital factor deficiencies, provide rapid, effective correction of factor-based coagulation disruptions. Three-factor (factors II, IX, and X) and four-factor (factors II, IX, X, and VII) varieties are available and are associated with minimal adverse events [32]. Recombinant factor VIIa has been associated with normalization of conventional coagulation tests, and decreased transfusion requirements [33]. Anti-inhibitor binders have also been utilized in specific circumstances, such as coagulopathy in the presence of novel anticoagulants. Recently, a dabigatran-specific antibody fragment has been released. Prior to the inception of idarucizumab, no method of therapeutic reversal was available for patients anticoagulated with dabigatran [34]. Currently, several agents are being developed to target coagulopathy resultant from factor Xa inhibitors, direct thrombin inhibitors, and other novel mechanistic medications.

Tranexamic acid, an antifibrinolytic, arose to the forefront of pharmacutetic hemorrhage control after the release of the CRASH-2 trial [35]. This study showed significant reductions in mortality. Subsequent studies confirmed its efficacy, and it is now frequently utilized as an adjunct during resuscitation of hemorrhagic shock [36–38]. Its efficacy, low cost, and wide availability make tranexamic acid an attractive adjunct to hemostatic control.
HISTORY OF HEMORRHAGIC SHOCK RESUSCITATION

The modern-day trauma system owes a large debt to combat casualty care. Techniques from system development to operating room procedures have their roots in battlefield medicine. Resuscitation is no stranger to advancement during wartime as well. To understand the advancements made and differences that exist with modern combat resuscitation strategies, it is important to understand the history of combat resuscitation.

Empiric crystalloid administration owes its roots to strategies developed in the Vietnam War. Based on research by Shires [42,43], Dillon [44], and others, the need for volume resuscitation was brought to the forefront to replace an interstitial volume debt, secondary to intravascular movement in hemorrhagic shock. High-volume crystalloid resuscitation strategies were used to replace volume loss encountered by the bleeding soldier in ratios of 3:1 to as high as 8:1. The physiology was sound, but outcomes were disappointing, as survival rates did not improve. In fact, the adopted strategy of large-volume IV fluid administration spawned its own set of complications, most notably the emergence of Da Nang lung, known now as ARDS. Reports linking ARDS to crystalloid resuscitation and subsequent immunologic effects appeared as early as 1967 [45].

Despite this, massive volume resuscitation strategies prevailed for more than 30 years. In the early 1990s, Rotondo and colleagues published the first major data on damage control surgery, employing early, rapid hemorrhage control, and temporizing measures to avoid the effects of ongoing massive resuscitation related to prolonged operative escapades [46]. This sparked a fury among traditionalists, but led to a series of manuscripts debunking the idea of benefit associated with large-volume resuscitation.

A report by the Institute of Medicine in 1999, as well as two consensus conferences held by Office of Naval Research, the US Army Medical Research and Material Command and the Uniformed Services University of Health Sciences, in 2001 and 2002, addressed concerns of resuscitation techniques, further delineating the adverse effects of large-volume resuscitation and giving recommendations for alternative
strategies. First noted was the paucity of Level I and II data to support
the then standard of care. Second, the immunologic activity of common
IV fluids and deleterious effects of high-volume resuscitation were best
defined by complications related to their use. Third, the reports
supported the initial battlefield use of low-volume hypertonic saline
(HTS) resuscitation [47]. A 250-mL bolus of HTS was chosen based on
research showing decreased neutrophil activation as well as increased
oncotic properties. Fourth, triggers for fluid resuscitation were defined as
systolic blood pressure < 80 mm Hg or the absence of palpable radial
pulse, decreasing blood pressure, or altered mental status with no
confounding brain injury [48]. This protocol allowed for “permissive
hypotension” during resuscitation until definitive hemorrhage control.
The goal was not to return blood pressure to normal, but rather to target
clinical goals of mentation and palpable pulse. These protocols were
developed with several civilian trauma studies in mind, showing survival
benefit to limited initial resuscitation [49]. The combination of a large
number of studies near the turn of the millennium ultimately culminated
in a complete 180-degree shift from the high-volume crystalloid
resuscitation seen in the Vietnam War. Currently, an injured soldier with
a palpable pulse and is awake and alert will have an IV placed, but no
volume will be infused. Oral hydration is encouraged, and rapid
evacuation is undertaken. If fluids are given, they are in low volume and
hypertonic in nature.

The concept is simple—without effective hemostasis, no amount of
resuscitation will effect a mortality benefit. In the Iraq and Afghanistan
Wars, the goal of resuscitation changed—from early volume resuscitation
to early hemorrhage control. With this objective highlighted, tourniquets
were reintroduced, and pharmaceutic adjuncts like recombinant factor
VIIa and tranexamic acid were added to the armamentarium to aid
cessation of hemorrhage [37].

Rural, marine, or mountainous areas typically require longer transport
times and represent some the civilian austere environments. In these
scenarios, much of the same wisdom gained from combat research should
be utilized, with minimal prehospital resuscitation prior to arrival at
definitive care. Once arriving at the tertiary facility, however,
resuscitation may begin with the same tenant—crystalloid resuscitation is
a thing of the past. Blood component therapy is now utilized early, rather
than after several liters of lactated Ringers or saline. Higher ratios of
plasma to red blood cells (RBCs) have been a point of study in recent
years, with ratio of 1:1 showing improved outcomes [50]. Highlighting the
value of replenishing specific blood components early in hemorrhagic
shock resuscitation.
INITIAL RESUSCITATION

Previously, initial resuscitation of hemorrhagic shock involved large-volume fluid resuscitation and maintenance of normothermia. Although these methods aimed to address two of the three components of the lethal triad, coagulopathy was largely ignored. Today’s resuscitation techniques specifically target the coagulopathy of hemorrhage through the concept of damage control resuscitation.

Damage control resuscitation focuses on several key goals, and begins immediately upon arrival to the emergency department. The first of which is to maintain a slightly lower-than-normal systolic blood pressure of approximately 90 mm Hg. This serves to limit clot disruption by allowing some degree of stasis to occur, increasing the chance for clot development, and strengthening. Peripheral vasoconstriction is preserved, and perfusion to vital organs is increased with permissive hypotension. Conversely, large amounts of IV fluids will reverse peripheral vasoconstriction and, without hemorrhage control, will ultimately worsen blood loss. Excessive or misdirected fluid resuscitation to achieve normal hemodynamics will lead to dilution of existing clotting factors, aggravating coagulopathy and exacerbating hemorrhage. The benefits of permissive hypotension were first recognized, and eloquently described, over 100 years ago by W.B. Cannon. His observations of the deleterious effects of copious volume resuscitation prior to hemorrhage control persist today. The current evolving hypotensive resuscitation literature continues to show improved mortality and morbidity in both traumatic and nontraumatic bleeding events [51].

Second, damage control resuscitation directly addresses the coagulopathy of hemorrhage. Fluid resuscitation commences with blood component therapy. As described earlier, crystalloids lack the essential elements necessary to combat the coagulopathy of hemorrhage, and are evidenced to exacerbate inflammatory dysregulation. Coagulopathy and inflammation are suppressed through administration of early plasma and platelets. These components also provide volume resuscitation, thus achieving both the first and second goals of the initial resuscitation. For patients in hemorrhagic shock, directly addressing hyperfibrinolysis is accomplished with tranexamic acid, which is most efficacious within 3 hours of injury. It acts to compete with plasmin, blocking fibrinolysis. Other antifibrinolytic pharmaceuticals are available, such as ε-aminocaproic acid. Concentrated clotting factors, such as prothrombin complex concentrates and recombinant factor VIIa, have the benefit of rapid repletion of essential clotting elements, with the effects within minutes of infusion, and should be considered in severely injured or
hemorrhaging patients.

Third, blood component therapy serves not only to maintain the above state of permissive hypotension while replenishing the stores of circulating procoagulants but also to optimize oxygen delivery in the interlude prior to, and during surgical, endoscopic or interventional hemorrhage control. Increasing oxygen delivery through augmentation of the blood’s oxygen-carrying capacity with red cells minimizes tissue oxygen debt in the setting of compromised circulation more so than crystalloid preparations. By relieving oxygen debt through increased oxygen delivery, acidosis is quelled because aerobic metabolism is supported and lactate production is limited. Decreased acidosis is crucial for normal global cellular and enzyme function.

Although there are clear benefits to blood component resuscitation, the optimal ratio of blood component therapy continues to be studied. A variety of ratios (fresh frozen plasma (FFP):PLT:RBC) exist to closely mimic the constituents of whole blood transfusion, which, in civilian centers, is rarely available. Early platelet and plasma administration have been associated with decreased mortality. In the PROMMTT study, investigators noted a three to fourfold increase in mortality in patients who received a 1:2 (FFP:RBC) transfusion ratio in the first 6 hours, as compared to those who received a 1:1 transfusion ratio [52]. This large, multicenter study showed clear benefit of early plasma initiation in the setting of hemorrhagic shock. More recently, Holcomb and colleagues tested the differences between 1:1:1 and 1:1:2 (FFP:PLT:RBC) ratios, and found equivocal mortality rates at both 24 hours and 30 days between the two. However, fewer deaths from exsanguination were noted in the 1:1:1 group [50]. Early, high-ratio transfusion of plasma and platelets aids not only in correction of coagulation dysfunction, but restores volume with necessary coagulation components shed during hemorrhagic shock.

Massive transfusion protocols have been widely adopted at both major centers and smaller hospitals. Development of these protocols has been associated with lower mortality rates. Although the term “massive,” implies a greater volume of products, multiple studies have shown decreased overall product usage when these protocols are effectively utilized early in the resuscitation. Several reasons exist to explain this somewhat paradoxic finding. First, by limiting crystalloid resuscitation, blood loss is lessened and dilutional coagulopathy is curbed, which ultimately will result in less product transfusion. Second, early activation allows for efficient optimization of the tenets of damage control resuscitation, resulting in less acidosis, improved organ function, and less
blood loss while hemorrhage is controlled. Third, for a patient presenting with hemorrhagic shock, predetermined massive transfusion protocols offer a streamlined method of delivering product to the patient while assuring that appropriate component ratios are maintained. Some published indicators for massive transfusion include (1) INR > 1.5, (2) BD > 6, (3) systolic blood pressure < 90 mm Hg, (4) hemoglobin < 11 g per dL, (5) heart rate > 120, and (6) positive FAST scan. The more of these factors that are present, the more likely the patient should undergo massive transfusion, with early plasma administration in a fixed-ratio paradigm.

Damage control resuscitation strives to reach a balance between achieving optimal physiologic function, while limiting the unwanted effects of the resuscitation itself, and is most useful from the time of presentation through the period of definitive surgical, endoscopic, or interventional hemorrhage control. It must expeditiously be initiated upon arrival in the emergency department, often with limited information. Prolonged resuscitation should not delay definitive hemorrhage control in order to achieve distant hemodynamic or physiologic goals. Time spent in the emergency department equates to lost time in the operating room, endoscopy, or interventional suites where damage control resuscitation may be continued and decisive hemorrhage control obtained. The initial phase continues through the operative intervention, and damage control principles are upheld by targeting the above physiologic goals. To this end, damage control surgery is often performed, which consists of surgical hemorrhage control, limitation of contamination and temporary closure, deferring definitive repair of non–life-threatening injuries until physiologic correction is achieved in the intensive care unit (ICU) in the second resuscitative phase.
ONGOING RESUSCITATION

While initial resuscitation of hemorrhagic shock is to serve as a bridge to operative, interventional, or endoscopic hemorrhage control, ongoing resuscitation following hemorrhage aims to restore normal physiologic parameters to ensure adequate oxygen delivery to resume normal bodily functions once hemorrhage has ceased. Despite effective damage control resuscitative measures, patients often exhibit varying degrees of physiologic instability in the ICU. Similar principles exist in the ongoing resuscitative phase, which is typically undertaken in the ICU. Patients arriving from the operating theater may remain hypovolemic, coagulopathic, hypothermic, and acidotic, necessitating further intensive management to achieve a successful resuscitation. Endpoints of resuscitation should be aggressively targeted in this phase to ensure rapid resolution of metabolic derangements that may have occurred during the preceding interventions.

Endpoints of Resuscitation

Traditional endpoints of resuscitation, such as heart rate, blood pressure, and urine output, are grossly inadequate as sole markers of physiologic normalization. Although these common methods provide insights into the overall clinical picture, they fail to accurately demonstrate resuscitation success. Confounding variables abound when considering these easily attainable, yet simplistic determinations. For example, heart rate is altered by a variety of mechanisms that may be unrelated to the adequacy of resuscitation. Pain and anxiety commonly cause tachycardia, whereas the widespread use of β-blockers and other cardiac medications may prevent it—rendering heart rate less useful. Urine output has long been utilized as an endpoint signifying the adequate restoration of perfusion to an end organ. However, oliguria may be present despite completion of resuscitation. CT evaluation is ubiquitous, and often utilizes IV contrast which commonly results in acute tubular necrosis despite aggressive resuscitation. Medications, specifically antibiotics, are known to cause acute interstitial nephritis. Additionally, the initial hypoperfusion event may have caused direct tubular injury resulting in oliguria, despite adequate resuscitation. Managing oliguria with large volumes of resuscitation fluid will inevitably result in the undesirable consequences of overresuscitation. Conversely, entities such as diabetes insipidus and cerebral salt wasting cause polyuria and may falsely reassure the clinician.

Hemorrhagic shock occurs as the result of hypoperfusion, and thus
markers of hypoperfusion should be sought as valid endpoints. An arterial blood gas is commonly touted as the most beneficial laboratory test in the resuscitation of a patient in hemorrhagic shock because of the rapid, comprehensive information gained, including BD. The BD assumes a normal pCO₂, which is a crucial point to consider, because it allows for the true metabolic derangement to be elucidated. Clinicians typically examine the pH, and may miss significant acidosis, especially if the patient is compensating with tachypnea. For this reason, the BD is a test that requires virtually no analysis, and provides a simple number that, in hemorrhagic shock, is an accurate marker of perfusion. Through the mechanisms described earlier in this chapter, acidosis results as a function of hypoperfusion and anaerobic metabolism at the cellular level. As this acidosis worsens, BD becomes more negative. An initial BD less than −6 is associated with the need for massive transfusion and damage control resuscitation practice implementation. Similarly, a persistent BD following hemorrhage control suggests the need for further resuscitation. Multiple studies have shown benefits of using the BD as an endpoint of resuscitation [53,54]. The goal should be a rapid normalization of the BD. Decreased mortality is associated with normalization of the BD within the first 24 hours of hospitalization. Some issues with BD warrant mention however. If sodium bicarbonate is employed in the initial resuscitation phase, the BD becomes useless, secondary to the addition of exogenous base to the equation. Only in the most severe acidosis cases should bicarbonate even be considered. Another relative indication for bicarbonate administration is to increase the effectiveness of resuscitation adjuncts, such as prothrombin complex concentrate or recombinant factor VIIa, which have decreased efficacy below a pH of 7.2. The BD may be confounded by other acidic states, such as hyperchloremia, which is typically iatrogenic in nature. Additionally, BD often lags behind the resuscitation, and its continued pursuit may lead to overresuscitation. When the BD persists, the presence of a missed injury or ongoing causes for hypoperfusion should be reviewed.

To counter the issues associated with BD, serum lactate is employed. In the setting of acute hemorrhagic shock, increases in lactate are the result of tissue and cellular mitochondrial dysfunction, and thus lactate provides insights into tissue perfusion. Parallel physiologic hypoperfusion mechanisms will cause the level of lactate to increase, secondary to anaerobic metabolism. Similar to BD, lactate clearance within 24 hours has been shown in many studies to be associated with lower mortality rates [55,56]. Several societies have incorporated lactate
into their resuscitation guidelines, including the Society of Critical Care Medicine and the Eastern Association for the Surgery of Trauma; and an internal consensus conference on hemodynamic monitoring has recommended utilization of lactate clearance as an endpoint of resuscitation. Lactate clearance is affected by hepatic function, and, for those patients with either underlying or acute hepatic insufficiency, elevated lactate concentrations may persist secondary to decreased clearance by the liver and may be misleading in these circumstances. Some have further criticized the ability of lactate levels to determine perfusion adequacy by citing the multiple aerobic processes, including glucose utilization in the setting of hyperglycemia, as potential nonperfusion-related causes for hyperlactatemia. However, many consider lactate one of the most useful endpoints in the resuscitation of hemorrhagic shock.

Adequate tissue perfusion depends upon both oxygen delivery and tissue oxygen demand. This supply–demand relationship can be determined by examining central venous oxygen saturation (ScvO₂) measurement from a central venous catheter. Normal physiologic conditions incur approximately 25% oxygen extraction at the tissue level, resulting in a ScvO₂ of 75%, given an arterial saturation of 100%. When tissue demand increases, or oxygen delivery decreases, as in hemorrhagic shock, more oxygen is extracted, decreasing ScvO₂. ScvO₂ has been shown to be a marker of both fluid responsiveness and reinstatement of normal perfusion [57]. By restoring normal cardiac output with volume administration, preload and afterload optimization, and inotropic support; the delivery component of ScvO₂ is corrected. Complexity arises, however, in addressing the demand component of ScvO₂. Peripheral vasoconstriction, as described earlier, is a compensatory mechanism in the face of hypovolemia. This vasoconstriction ultimately leads to decreased tissue oxygen extraction and a rising ScvO₂. Conversely, in hemorrhagic shock tissue, oxygen demand and concomitant extraction are typically increased secondary to tissue-level hypoxia, resulting from acute hypovolemia and hypoperfusion. Increased oxygen extraction in response to hemorrhage leads to a delivery-dependent state and declining ScvO₂. These two competing forces have resulted in an argument against the efficacy of ScvO₂ as a resuscitation marker and work to confuse the interpretation of ScvO₂. Despite these intricacies, ScvO₂ remains an endpoint of interest, and abnormal elevations or decreases in ScvO₂ should prompt the clinician to adjust resuscitation based on results.

In hemorrhagic shock, restoration of normal oxygen delivery (DO₂) is the ultimate goal, making this calculated value extremely useful for
determining sufficiency of resuscitation. The equation is defined as the product of arterial oxygen content and blood flow, and involves three main components: cardiac output, hemoglobin, and oxygen saturation (SaO$_2$). The contribution of partial pressure of oxygen is negligible and is often omitted in bedside calculations of DO$_2$. With the equation, we simplify the concept of perfusion, by separating it into two main determinants—flow and content. To address arterial oxygen content, first the SaO$_2$ is optimized through oxygen administration, increased FiO$_2$, or through ventilator methods to increase oxygenation. Hemoglobin is then optimized, keeping in mind the clear benefit of restrictive transfusion strategies shown in virtually all patient populations. Next, flow is maximized via optimization of cardiac output, which typically equates to targeting stroke volume through ongoing resuscitation or application of inotropic agents. Through these methods, normalizing oxygen delivery represents a valid and complete endpoint of resuscitation for hemorrhagic shock. Like the endpoints described earlier, DO$_2$ is not without limitation. In states of decreased tissue oxygen extraction, DO$_2$ may not coincide with cellular perfusion. Additionally, advanced monitoring is required to obtain stroke volume measurement, and depending upon the device used, significant error may be introduced into the equation.

**Coagulation Endpoints**

Many damage control resuscitation measures are directed at controlling the early coagulopathy of hemorrhage. The ongoing phase of resuscitation continues this focus. Conventional coagulation tests are helpful, and provide insight into ongoing coagulopathy. Considering the above endpoints, the clinician should consider normalizing coagulation function with plasma, platelets, cryoprecipitate, or pharmacologic means. Understanding each of the blood components and when to utilize them is crucial in the resuscitation of hemorrhagic shock. TEG and rotational thromboelastometry (ROTEM) have gained wide acceptance over the last decade owing to the ability to help guide resuscitation, and serve as a set of endpoints specifically relating to the coagulopathy associated with hemorrhage. Developed in 1948 to detect congenital factor deficiencies, this technology has broadened its use to hemorrhage of all types. TEG is a dynamic test that measures both the formation and lysis of the clot. Results are presented graphically and numerically and allow for a global assessment of clotting function, by illuminating abnormalities at specific sites in the clotting cascade and offering detailed information regarding coagulation function.

TEG and ROTEM share many similarities; however, the nomenclature
differs between the two. Abnormalities in clot initiation are measured by R (TEG) or CT (ROTEM). Clot initiation is dependent upon clotting factors. Therefore, a prolonged R or CT value corresponds to a deficiency in clotting factors. Prolongations are commonly seen with anticoagulant use and in the presence of factor inhibitors. Therapies include plasma transfusion, prothrombin complex concentrates, and recombinant factor VII. As the clot develops, the tracing diverges and becomes parabolic in shape. The initial angle of this divergence is known as alpha (α). The α corresponds to the rapidity of clot development, and is mainly dependent upon fibrinogen, with a minor role played by platelets. A steep angle indicates overly rapid clot development, whereas a gradual angle indicates a slowly developing clot. Hypofibrinogenemia and hyperfibrinolysis often result in a low α value. Therapies include plasma, which has the greatest amount of fibrinogen, and cryoprecipitate, which has the highest concentration of fibrinogen. As the clot strengthens, the parabolic curve peaks, resulting in the maximal amplitude (MA) (TEG) or maximum clot firmness (MCF) (ROTEM) of the clot. This is largely dependent upon platelets, with fibrinogen and platelet–fibrinogen interactions contributing to a lesser extent. Low MA/MCF values are seen with thrombocytopenia and in the presence of antiplatelet agents, such as aspirin or clopidogrel. Treating low MA/MCF values is limited to platelet transfusion only. The down-sloping TEG tracing represents the time for clot lysis. Normal lysis at 30 minutes, LY30 (TEG) or CL30 (ROTEM), is 0%. Minor increases in lysis (3% to 8%) are associated with increased mortality and should be rapidly addressed. Therapy includes antifibrinolytic medications, such as tranexamic acid and ε-aminocaproic acid. Plasma and cryoprecipitate may also be employed to replace lost fibrinogen, but the mainstay of treatment is to cease hyperfibrinolysis with pharmacologic means [58].

Employing targeted pharmacologic and transfusion strategies based on TEG measurements allows for normalization of coagulopathy, while limiting untoward effects of overresuscitation or underresuscitation. Additionally, it may result in fewer transfusions, which in turn will decrease complications related to transfusion.

**Monitoring**

Today’s ICUs utilize advanced technologies to determine volume status and resuscitation parameters. The Swan–Ganz pulmonary artery catheter (PAC), since its introduction in 1970, has provided a wealth of
information regarding hemodynamics to a large variety of patient populations. However, multiple, large randomized trials have failed to show a mortality benefit when PAC parameters were used to guide resuscitation [59,60]. And, in some trials, higher mortality, increased morbidity, and larger volume fluid resuscitation were seen with PAC use. Additionally, with less-invasive monitors becoming more and more available, the PAC has fallen out of favor. The benefits of the PAC, however, should not be understated in certain instances. Patients with significant arrhythmias or those with pulmonary hypertension may benefit from PAC catheterization, because noninvasive methods frequently fail to demonstrate accurate hemodynamic results. Furthermore, perioperative use of PACs to guide resuscitation has shown in multiple studies to show a mortality and morbidity benefit [61]. For hemorrhagic shock, the PAC may provide information not available from noninvasive methods and, therefore, should be considered in select patient populations.

In addition to PACs, a variety of minimally invasive and noninvasive techniques are available to rapidly determine endpoints of resuscitation. Arterial waveform analysis methodologies have seen widespread use in recent years. Continuous pulse contour cardiac output monitors (PiCCO; Phillips) utilize proprietary thermodilution arterial catheters, typically inserted in the femoral artery, to determine cardiac output through pulse contour analysis. Frequent calibration is necessary, and a learning curve exists both from a physician and nursing point of view [62]. Lithium dilution cardiac output (LiDCO; LiDCO Limited) is measured through the injection of lithium via a central venous access line. The concentration changes of lithium are then measured with a lithium-sensitive sensor attached to an existing arterial line. Again, multiple daily calibrations are necessary; however, a variety of derived variables, including cardiac output, are readily calculated and have been shown to be equivalent to thermodilutional techniques [63]. Arterial waveform monitors (Vigileo; Edwards Lifesciences) provide cardiac output measurement through existing arterial lines, and do not require injection-based calibration. By measuring the pulse pressure variations, stroke volume is calculated and cardiac output is derived. Although typically less precise than the above dilutional methods, arterial waveform monitors provide information using existing catheters with minimal training [64].

Noninvasive methods of cardiac output determination continue to be developed. Ultrasonic cardiac output monitoring (USCOM; Uscom Ltd.) utilizes an ultrasound probe placed at the sternal notch to measure beat-to-beat variability, cardiac output, and systemic vascular resistance. It requires minimal training and has been validated against thermodilution. Obesity may be a barrier to utilizing this method, and may increase error rates in measurements [65]. Another noninvasive device (NICOM;
Cheetah Medical) uses bioreactance to measure phase shifts and amplitude after passing a current between electrodes placed on the chest. The phase change correlates well with changes in stroke volume and aortic blood volume. This noninvasive monitor has shown good correlation and reliability both with Doppler ultrasound and thermodilutional methods [66]. It is important to note that reliable monitoring is crucial to determining adequacy of resuscitation. Blind resuscitation invariably misses the mark, resulting in either overresuscitation or underresuscitation and worsened outcomes.

**Fluids and Component Therapy**

Historically, crystalloid solutions were almost exclusively utilized in resuscitation following hemorrhage. Traditional regimens called for infusing crystalloids while awaiting blood products from the blood bank, with repeated bolus doses as necessary. Following at least 2 L of crystalloid infusion, PRBC were considered. Unfortunately, this approach led to worsened coagulopathy, worsened organ failure, and overall outcomes. Recent evidence has shown improved mortality and morbidity with earlier use of blood products, including plasma transfusion. As stated previously, a key component to both early damage control resuscitation and ongoing resuscitation in the ICU is that crystalloids offer little benefit for hemorrhagic shock. Unlike patients in septic shock, hypotension and hemodynamic collapse are secondary to blood loss. This simple idea of replacing what was lost is at the cornerstone of hemorrhagic shock management. Crystalloid preparations inevitably are used to some extent, either as medication carriers or transfusion flushes. However, their use should be limited as much as possible—especially in the early phases of resuscitation, before hemorrhage control is gained. Once in the ICU, targeted and thoughtful use of crystalloid may be employed, but again holding true to damage control tenants. Fluid shifts occurring as the result of hemorrhage are often profound and worsened by large-volume IV fluid administration. Control of coagulopathy and acidosis also falls victim to isotonic and hypotonic crystalloid volume use. HTS is one crystalloid formula that has proven beneficial. Solutions of 3%, 5%, and 7.5% are commercially available. High concentrations of sodium chloride delivered to the vascular system favor the flux of water from the interstitial space and from the cells to augment the blood volume. This results in a rapid restoration of intravascular volume. Infusions of small amounts of these solutions lead to hemodynamic responses equivalent to much larger volumes of crystalloid solutions. This is advantageous because of both the rapidity of the response and the limited volume necessary to achieve the same goals. Recent work suggests these fluids decrease the activation of neutrophils, modulate
cytokine and adhesion molecule expression, and suppress the production of reactive oxygen species. These immunomodulatory effects have been shown to decrease the risk of multiple organ dysfunction syndrome [67]. Proponents believe that the smaller volumes lead to less tissue edema and associated potential complications. Once fluid is drawn into the vascular space, sodium chloride is diluted and equilibrates across the fluid spaces of the body. As this happens, the effect of the HTS is gradually lost. Increases in mean arterial pressure are short-lived, with hemodynamic effects lasting only 15 to 75 minutes [68]. The largest potential danger with hypertonic solutions is hypernatremia. This may be accentuated in the previously dehydrated patient without additional extravascular fluid to donate to the vascular system. Although some rapid and transient hypernatremia seems to be tolerated, caution in administration and careful monitoring of sodium levels are important in the safe use of these solutions.

Whole blood contains all of the factors lost by the bleeding patient, including plasma proteins, clotting factors, platelets, and white blood cells, as well as erythrocytes. Although fresh whole blood is a superb resuscitation fluid, it has a short storage life and, therefore, has limited use in the typical civilian setting. Additionally, infectious disease testing and blood banking inventory management issues have made whole blood largely unavailable. However, whole blood is used in many centers, and clinical studies on whole blood are underway for civilian trauma patients. Prospective data collected in these studies may present an impetus for change in blood banking and provide access to this useful and efficacious resuscitative fluid.

RBC transfusion is common for the resuscitation from hemorrhage, and should be utilized early in the process. Initial resuscitation practices often employ uncrossed blood products with O-negative; however, packed red blood cells (PRBCs) should be typed and cross-matched as early as feasible to avoid transfusion reactions. PRBCs can be stored for 42 days according to current Food and Drug Administration standards. However, detrimental effects of stored PRBCs can be related to their age. Hyperkalemia is a well-known problem with red cell storage, because potassium is lost into the PRBC supernatant over time. Increased risk of cardiac events, infection, multisystem organ failure, and mortality are also associated with older RBCs [69,70]. Despite safeguards, clerical errors lead to mismatched blood administrations, with a rate of fatal major ABO blood group reactions of between 1 in 500,000 and 1 in 2 million. Currently, the risk of infection from a transfused unit is 1 in
30,000 to 1 in 150,000 for hepatitis C, and 1 in 200,000 to 1 in 2,000,000 for human immunodeficiency virus [71].

The benefits of early plasma administration continue to be realized through multiple randomized trials. Plasma should be considered an initial resuscitation fluid in hemorrhagic shock, along with PRBCs. Thawed plasma is plasma that is stored for up to 5 days at 1°C to 6°C. This storage timeline is based on similar RBC storage guidelines and preservation of factors V and VIII; however, clinical data is lacking [72,73]. Because more centers are using earlier and increased amounts of plasma, thawed plasma is now routinely available at many trauma centers, and increasingly stored in emergency departments. Type AB plasma, the universal donor for plasma, is chosen initially before cross-matched product is available. Group A plasma has been shown to be a safe alternative to Type AB, and empiric utilization of Group A plasma may expand the use of massive transfusion protocols, and help encourage the use of early plasma transfusion where AB availability is limited [74]. Having thawed plasma available in the emergency department allows for the initiation of a protocol driven high ratio of FFP to PRBCs. Plasma transfusion risks of TRALI, infection, and multisystem organ failure increase at the rate of approximately 2% with each unit transfused [75]. However, these observations have been made in the context of higher survival among patients who received high ratios of FFP, suggesting that those patients survived despite the potential cost of sepsis and multisystem organ failure development.

Platelets are transfused in two different formulations. Pooled whole blood–derived platelets are generally transfused in six-unit increments from five to six different blood donors. Apheresis platelet units are derived from a single donor and are transfused in volumes approximately equal to 5 to 6 units of pooled whole blood–derived platelets. Because evidence continues to emerge, it is becoming clear that platelets, once an afterthought during traditional resuscitation practices, should be transfused at higher ratios. Many massive transfusion protocols include platelets in the first or second tier of the transfusion guideline. Improved outcomes have been seen when fixed-ratio transfusion strategies include platelets early in the schema. Platelet counts of less than 20,000 per μL should always be corrected in any bleeding patient, whether or not a life-threatening injury has been identified. If the patient has a known history of antiplatelet use within the preceding 7 days, it may be necessary to transfuse platelets despite a platelet count greater than 50,000 per μL, particularly in those patients with head injury or those being managed nonoperatively for significant solid organ injury. Platelet counts of less than 100,000 per μL are a relative indication for platelet transfusion in the head-injured patient with evidence of intracranial hemorrhage, whether as a single-system injury or as part of multisystem injuries. It is
possible that we have been overly restrictive in the use of platelet transfusions, because recent data suggests that increased and early use improves survival [52]. Both pooled and apheresis platelets are stored at room temperature for up to 5 days. Bacterial contamination remains the greatest risk of platelet transfusion; however, apheresis platelet units have been shown to have lower risk of infection because they are derived from a single donor.

Cryoprecipitate is a product of FFP that contains factor VIII, von Willebrand factor, fibrinogen, fibronectin, factor XIII, and platelet microparticles. The benefits of including cryoprecipitate in massive transfusion protocols have yet to be confirmed [76]. As a product of plasma, cryoprecipitate contains many of the constituents of plasma, only in concentrated, less voluminous form. For this reason, unless a specific coagulation defect is targeted, cryoprecipitate likely offers little benefit over FFP in the early resuscitation of hemorrhagic shock. Cryoprecipitate is made after centrifuging thawed plasma and removing the supernatant. It has a shelf life of 1 year when frozen at −20°C. Cryoprecipitate is customarily transfused in 10 unit bags, although this is highly variable. As a result of this practice, patients generally receive 2.5 g of cryoprecipitate per transfusion.

Vasopressor and Inotropic Support

Despite adequate volume resuscitation, some patients require additional pharmacologic means to attain hemodynamic goals. In these patients, selective use of vasopressor agents may be necessary. A keen understanding of each agent’s receptor targets and their resultant effects is required to effectively make use of vasopressors in the resuscitation of hemorrhagic shock. Norepinephrine is widely used, and is at the forefront of many algorithms aimed to treat critically ill patients. Acting weakly on $\beta_1$ receptors, norepinephrine mildly increases contractility, while it acts to strongly activate $\alpha_1$ receptors, affording potent vasoconstriction.

Bradycardia is commonly seen and is, therefore, not recommended for those with bradyarrhythmias. Dopamine acts on multiple receptors and is strongly associated with tachycardia and the development of tachyarrhythmia. At lower doses, it acts as a dopamine ($D_1$) receptor agonist, and may produce vasodilation through action on $\beta_2$ receptors. The so-called “renal dose” dopamine, at low doses, has not been shown to improve renal perfusion or treat renal insufficiency, and although theoretical advantages exist, clinically it has no benefit. At somewhat higher doses, dopamine triggers $\beta_1$ receptors and increases contractility and heart rate. With increasing doses, $\alpha_1$ receptors are activated and vasoconstriction results. Dopamine is typically a second-line agent for
most situations relevant to hemorrhagic shock, because of the risk of tachyarrhythmia is increased in patients who are already tachycardic.

Epinephrine is a powerful agent acting strongly on both $\alpha$ and $\beta$ receptors. In the case of cardiac arrest, 1 mg bolus doses remain a mainstay of treatment. When higher doses are used, tissue ischemia becomes more likely. High-dose epinephrine infusions worsen acidosis and ultimately may result in cardiac ischemia, and therefore are not recommended. Lower doses, however, may be beneficial as either intermittent boluses or infusions. Particular benefits may be seen prior to anesthetic induction for procedural hemorrhage control.

Phenylephrine is a pure $\alpha$-agent, effecting potent vasoconstriction. Care should be taken when beginning a phenylephrine infusion in patients with hemorrhagic shock. These patients are typically maximally vasoconstricted via endogenous catecholamine release, and cardiac output is being sustained by the patient’s tachycardia. Further vasoconstriction, without stimulation of $\beta$ receptors, will worsen cardiac output by causing a reflex bradycardia, and reduced cardiac output. Additionally, phenylephrine infusions in elderly patients may increase afterload beyond that which the aging heart can function, causing acute heart failure and precipitous drop in cardiac output.

Vasopressin has been increasingly utilized in the resuscitation of patients following hemorrhage. Evidence suggests endogenous vasopressin stores are rapidly depleted in response to hemorrhage, and replacement with a low-dose infusion is warranted when hemodynamic profiles are not optimized. The greatest benefit appears to be when vasopressin is used in conjunction with other vasoactive medications, such as norepinephrine. When norepinephrine doses are greater than 12 $\mu$g per minute, concomitant vasopressin infusion has been shown to allow norepinephrine to be titrated down, while maintaining desirable hemodynamics. High-dose infusions (>0.04 units per minute) are strongly associated with coronary ischemia and are not recommended.

Dobutamine and milrinone are two inotropic agents that typically have limited use in hemorrhagic shock. Dobutamine, a pure $\beta$-agonist, has a strong effect on contractility and heart rate. It is also associated with vasodilation, and may result in up to a 10% drop in systemic vascular resistance. Milrinone, a phosphodiesterase inhibitor, increases contractility by increasing cyclic adenosine monophosphate. It too, acts as a vasodilator, and preferentially vasodilates the pulmonary vascular bed. Owing to their vasodilating properties, both of these pharmaceuticals offer limited benefit in the resuscitation following
hemorrhage. In selected circumstances, principally preexisting heart failure, they may be utilized, but invasive monitoring is necessary to fully appreciate these benefits.

Additional Therapies

Coagulopathy may persist despite aggressive initial treatment. It is important to reevaluate coagulopathy within the first 48 hours of the ICU stay. Preexisting conditions, such as cirrhosis, may prevent adequate coagulopathic control without repeated dosing of medications, such as vitamin K, prothrombin complex concentrates, or plasma (if volume is necessary). Similarly, hyperfibrinolysis may still be present, and require dosing of tranexamic acid. If renal failure is present, the presence of uremic platelet dysfunction should be considered and treated with high-dose DDAVP.

Steroids have been studied in many shock states; however, they have shown little benefit in hemorrhagic shock. One area of interest where steroids may have benefit is in the realm of acute acquired adrenal insufficiency. In patients with persistent hypotension, despite adequate volume resuscitation, a random cortisol level and empiric dosing of either hydrocortisone or dexamethasone should be considered. Many clinicians use clinical judgment to guide administration of steroids in the face of a “relatively” low serum random cortisol. The cortisol stimulation test is controversial, but when used, the patient’s cortisol level should increase a minimum of 9 μg per dL above baseline upon administration of cosyntropin.

Glycemic control should be initiated upon arrival to the ICU. Hyperglycemia encourages a proinflammatory state, and results in worsened outcomes. Targets should be reasonable, because iatrogenic hypoglycemia is associated with worsened outcomes as well. Nutritional support should be initiated as early as prudent, depending upon the patient’s physiologic state. Intra-abdominal hemorrhage and subsequent operations often preclude early enteral feeding, as do the necessity of vasopressor agents. Most vasoactive medications decrease splanchnic circulation, which increases the risk of tube feed necrosis and other nutritionally related enteric disasters.

Evidence continues to emerge regarding the use of thromboembolic prophylaxis in the setting of hemorrhage. As directed treatment of coagulopathy is associated with improved outcomes, so is thromboembolic prevention. Hemorrhaging patients often are in a prothrombotic and paradoxically coagulopathic state. Overactivation of the clotting cascade combined with stasis from hypotension and vascular damage from the inciting event complete Virchow’s triad, and therefore put patients at increased risk for thrombotic events. Once hemorrhage
control has been demonstrated, thromboembolic prophylaxis should be initiated. In most cases, waiting more than 24 hours is unnecessary, and leads to higher rates of thromboembolic events.

Home medications should be reviewed and begun as necessary. Preinjury statin use is associated with increased rates of myocardial ischemia when these medications are not restarted upon admission. Withholding β-blocker medications may result in rebound tachycardia and tachyarrhythmias, and increase risk of cardiac ischemia. Diuretics are typically detrimental until the patient is beyond the resuscitative phases, and are generally withheld until stability is demonstrated. In those patients who take diuretics regularly, however, special attention is warranted in regard to volume overloaded states, and the development of pulmonary edema. Anticoagulants should be restarted with caution. Certain conditions, such as patients with mechanical heart valves or recent percutaneous coronary stents, may require anticoagulant or antiplatelet agents to be restarted as soon as possible. An accurate and thorough history is essential to obtain, especially in the aging population.
SUMMARY

Shock following hemorrhage represents a significant, multifaceted process impacting a significant number of patients. Early recognition is crucial to improve outcomes. Once recognized, hemorrhage control must rapidly be obtained to prevent further physiologic derangements, for without it, any resuscitation strategy is futile. Hemostatic adjuncts, both topical and IV, may be utilized to reach this goal. Damage control principles, with targeted treatment of coagulopathy, early use of plasma, and limited crystalloid volume, should be employed in patients at risk for exsanguination. Before, during, and after hemorrhage has ceased, resuscitation efforts must proceed with goals to normalize hemodynamic, coagulation, and perfusion parameters. Resuscitation endpoints should be targeted, with the combined use of advanced monitoring techniques, laboratory results, and clinical judgment.

INTRODUCTION

The number of preventable deaths from traumatic injuries worldwide is unfortunate, numbering in the millions annually. In the United States, trauma constitutes a public health crisis and is responsible for over 130,000 lives lost annually. Trauma is now the fourth leading cause of death in the United States based on 2013 statistics published by the Centers for Disease Control and Prevention (CDC). It also remains the leading cause of death among those aged 1 to 44 years. Trauma represents the second highest potential years of life lost, behind only malignant neoplasms. The impact of trauma goes beyond the number of deaths. For every death from trauma, there are 20 individuals who are admitted to the hospital and over 200 Emergency Department visits. The cost of injuries in terms of lost wages, and direct and indirect medical expenses, is estimated to exceed $400 billion annually [1–3].
BACKGROUND

Trauma is a time-sensitive disease. Classically trauma-related deaths were described in a trimodal fashion. Based on this early model, nearly half of all deaths occur immediately at the time of trauma before any medical intervention. The second group of patients reflects those who have ongoing bleeding and injuries that require critical care and may need operative intervention. This group best demonstrates the time-sensitive nature of trauma and is best described by the “Golden Hour” concept. Badly injured trauma patients have a “golden hour” during which time they should be transported to a trauma center and their injuries addressed. The last group of patients reflects those with late mortality related to complications from this initial traumatic insult and resulting medical care.

Today, trauma systems are focused on the rapid transport of injured patients to the most appropriate level of care. This means transportation to a verified trauma center rather than simply the closest hospital with an emergency department. The goal of trauma systems is to get the right patient to the right facility at the right time for the best outcomes.
DEFINITIONS

Typically, trauma patients are individuals suffering from penetrating, blunt, or thermal trauma. Combinations of mechanisms may occur, as well as special circumstances such as blast, near drowning, or electrical injuries. Trauma patients need to be triaged to the most appropriate facility for care. Triage is based both on severity of injuries identified and on the risk of severe injury. The potential severity of injuries is important because the total sum of injuries is not known until the patient has been fully evaluated at the appropriate trauma center. Hemodynamic normalcy at a given point in time does not assure that the patient will remain that way.

Trauma centers are hospitals that have been designated by the state or other designating authority as qualified to care for injured patients. The American College of Surgeons (ACS) maintains a Verification Review Committee that recommends designation for hospitals at certain levels of care using criteria in their document “Optimal Care of the Injured Patient,” the sixth edition of which was published in 2015. There are usually a small number of trauma centers in a certain geographic area assuring that each receives an adequate volume of patients required to maintain clinical expertise. Most frequently, trauma centers are designated as Level I through Level IV (some states have also designated Level V trauma centers). Level I trauma centers provide the highest level of care, plus have research, teaching, and serve as a regional resource. Level II trauma centers are intended to also provide for the full spectrum of trauma care, but do not have the research and teaching requirements. Level III facilities do not provide the full spectrum of trauma care; they usually do not provide neurosurgical services. Level IV trauma centers provide trauma care commensurate with their existing resources and usually function as “points of entry” into the system.
HISTORY

The ACS in the 1920s established a committee to attempt to improve in-hospital management of traumatic injuries. This committee attempted to set standards for emergency room treatments and practices. There was some initial push for more involvement of prehospital first responders, but it was not until 1966, when the National Academy of Sciences and the National Research Council published “Accidental Death and Disability: The Neglected Disease of Modern Society,” that progress was made with prehospital care. This paper highlighted trauma as a major public health problem and made specific recommendations to reduce accidental death and disability. Subsequent national and state legislation included the Highway Safety Act and the National Traffic and Motor Vehicle Safety Act, which was the first effort to regulate traffic safety and reduce automobile-related death and injuries. Then in 1973, the EMS Systems Act identified trauma systems as one of 15 essential components of an EMS system and appropriated federal funds [4].
VERIFICATION AND DESIGNATION

The trauma system encompasses the complete care of the injured patient from the point of injury prehospital to the completion of the rehabilitative process. Important activities of that system include injury prevention, education, research, and financial viability. For this, there needs to be a lead agency established by each state that has the authority to create and execute policy for the injured patients, as well as designate the trauma centers to manage the injured patients. In order to receive a designation, a hospital or medical center has to demonstrate the standards of care established by the designating authority to achieve their level of trauma center, I, II, III, or IV. The trauma center is then evaluated and verified by either an internal team or an external reviewer, such as the ACS, as meeting the necessary criteria to be a trauma center in the system. This verification is then recommended to the lead agency of the state for designation of a trauma center. The lead agency regulates the quality of trauma systems components and establishes trauma triage guidelines.

The ACS Committee on Trauma (COT) wrote the “Optimal Hospital Resources for Care of the Seriously Injured” in 1976 and is presently on its sixth edition, now called the “Resources for Optimal Care of the Injured Patient.” Since the ACS established this document, it has served as the standard by which trauma systems function and the quality of care is provided. The ACS verification process consists of hospital site reviews to determine a given center’s quality of care and ability to manage seriously injured patients. This verification process is then often used by the state as the designating authority to either designate or maintain designation as a trauma center. Verification is currently for 3 years: the rationale being that hospital systems are usually in a constant state of flux and must be verified on an ongoing review process. The ACS–COT also reviews statewide trauma systems to make recommendations to the system as a whole for regional improvements [5,6].
QUALITY OF CARE

Early studies of trauma systems in California introduced the concept of preventable mortality. These studies were able to clearly identify a group of trauma patients, in nonregionalized trauma system areas, that died from inadequate care—preventable mortalities. This concept provided a tool that could be used to examine quality of trauma care in any region or system. It became increasingly clear that analyses of data were important for determining quality of care, trends, and preventable mortality. Trauma registries emerged as a required part of all ACS-verified trauma centers. Aggregations of these hospital-based trauma registries then developed as a result of state-sponsored trauma registries and research-oriented databases. With the ability to examine populations of trauma patients came the development of mathematical formulas calculating the probability of survival of an individual trauma patient and comparing quality of care at trauma centers based on patient survival [7].

Trauma registries continue to support the advancement of trauma care on a national scale. The National Trauma Data Bank (NTDB) is the largest aggregation of trauma patient data. It produces yearly reports and establishes benchmarks for patient care. The development of the ACS TQIP (Trauma Quality Improvement Program) has allowed individual centers to assess their own outcomes compared to national standards. These individualized reports allow institutions to understand areas in which they excel at or need improvement in. This focused feedback, compared to national standards, gives trauma centers specific information necessary to make targeted quality improvements. National aggregation of trauma patient data has allowed for several organizations to emerge and set guidelines for trauma care. AAST (American Association for the Surgery of Trauma), WEST (Western Trauma Association), and EAST (Eastern Association for the Surgery of Trauma) each publish practice guidelines for trauma centers. They use the wide breadth of available data to provide trauma centers with best practice guidelines based on available published evidence.

The ability to implement best practices at trauma centers requires education of both prehospital and hospital providers. The ACS–COT develops the prototype Advanced Trauma Life Support Course (ATLS) in 1978 [8]. The course has been adopted and managed by the American College as one of the most successful educational programs for doctors worldwide. ATLS lays out the framework for the management of trauma patients. Every trauma evaluation begins with a primary survey. The primary survey consists of an ABCDE assessment. In the primary survey, A is for airway, B is for breathing, C is for circulation, D is for disability,
and E is for exposure. A secondary survey follows, during which a head-to-toe physical exam is performed and pertinent history obtained. The concept of the primary survey is to identify the most life-threatening problems first and begin treatment immediately. The remainder of the ATLS teaches diagnostic and life-saving interventions, as well as emphasizing the need to transfer a seriously injured patient to a trauma center. ATLS has been introduced in over 50 countries worldwide and is available in numerous different languages.

As one examines the challenges and successes of trauma systems, it remains clear that all phases of care are equally important for the successful outcome desired. These phases are:

- **Identification/recognition of incident**: The first step in any system is to identify that an injury has occurred or the patient may succumb before medical care can be started. This happens not infrequently in rural and remote parts of our country. Even if the patient is found and transported to an appropriate trauma center, the delay in care may result in sepsis from open fractures not cared for in a timely manner or organ failure from delays or inadequate resuscitation. Some locations in our nation are so remote that even when the injured patient is recognized immediately, it can take more than 24 hours for him or her to arrive in a definitive care facility. The risk for poor outcomes is the same in either case.

- **Prehospital care and transport**: Prehospital care systems are extremely variable across the United States. These systems range from volunteer to government-employed professionals or contracted professionals. As the first responders to any accident, these individuals often are the first to provide lifesaving treatment. Quality EMS providers provide intensive care in the prehospital setting. Pre-Hospital Trauma Life Support (PHTLS) has been developed as a teaching tool for EMS and other prehospital providers to provide education and teaching about care of trauma patients. Inadequate or delayed care can have profound effects on outcomes. Many trauma systems set up regionalized trauma triage criteria that allow the more critically injured patients to bypass closer facilities in favor of higher-level trauma centers capable of providing more definitive care. This regionalization allows more critically injured patients to reach definitive care more quickly. This triage process is enabled by the national trauma field triage guidelines. These guidelines set up protocols for first responders to assist in the decision-making of when to bypass a closer hospital for a designated trauma center. The 2006 national field triage guidelines were reviewed again in 2011 against published data and published as *Guidelines for Field Triage of Injured Patients: Recommendations of the National Expert Panel on Field Triage, 2011* [9].
Emergency department (ED) care: The Emergency Department represents the advanced practitioners' first chance to evaluate trauma patients. Even in the ED, inadequate or delayed resuscitation may contribute to a worse outcome. This may happen many ways: too slow a resuscitation may result in prolonged hypotension with potential for organ damage—the brain being particularly susceptible. Conversely, over aggressive resuscitation in the face of some injuries such as brain injury or pulmonary contusion may also cause problems. In these cases, too much resuscitation fluid may result in unnecessary tissue edema. This will cause increased intracranial pressure and poor perfusion in the closed space of the skull. With the lungs, the leaky capillaries associated with pulmonary contusion will cause the contusion to worsen, with difficulty in ventilating and weaning the patient. Too aggressive crystalloid resuscitation in the severely burned puts the patient at increased risk of abdominal compartment syndrome. Inappropriate use of strictly crystalloid resuscitation, when blood/blood products are indicated, can lead to increased mortality. Systems at individual centers are critical for the timely and effective assessment of the trauma patient. At higher-level trauma centers, these systems are often resource-heavy with large teams of staff prepared to quickly evaluate and treat trauma patients. However, at smaller or more rural centers, there may be only a small team or an individual practitioner who is charged with this patient’s care. At these smaller facilities, prompt stabilization and transfer of critically injured patients to a higher-level center is essential.

Operating room (OR) care: Prior to intensive care unit (ICU) admission, many trauma patients will have required operative intervention. In the operating room, the trauma surgeon remains the principal manager of resuscitation. Although the surgeon is operating, other staff and resources are essential for effective patient care. Operating rooms must be capable and prepared with equipment and staff to explore any part of the body necessary. Inappropriate or inadequate resuscitation during operative intervention may worsen outcomes. As a result, anesthesia plays a critical role in the management of trauma patients in the operating room. Many centers have moved to a massive transfusion protocol both in the emergency department and in the operating room to help guide patient fluid management. These protocols focus on giving blood and blood products in predetermined ratios to optimize outcomes and trauma patient resuscitation.

ICU care: ICU critical care is essential for the management of the sickest trauma patients. Any and all organ systems can be adversely affected by trauma, and the ICU is critical in supporting and managing
these diverse set of injuries. Patients who arrive from the operating room may still be cold, acidotic, or coagulopathic; and it is incumbent on the trauma system to have effective ICU care to manage the significant burden of disease. The ICU provides an opportunity to review and compile the data that has been collected to date and continue to evaluate the trauma patient for additional injuries: a so-called “tertiary survey.” Central lines placed urgently in less than sterile conditions are removed and replaced with new sterile lines; blood work and physiologic monitoring are used to provide focused care and to direct care guided by end points of resuscitation. Other chapters in this section give details for the care of shock, resuscitation, management of sepsis, multiple organ dysfunction syndrome, traumatic brain injury, spinal cord injury, thoracic and cardiac trauma, abdominal trauma, burn management, and orthopedic injuries.

- **Ward care after leaving the ICU:** Critical care trauma patients will need close follow-up on the trauma center wards. Sepsis may occur on the floor with MOD syndrome as well. The physicians following these patients must be capable of early recognition of these problems and institute immediate therapy when such problems are recognized. High-functioning trauma systems are not devoid of complications, but they do have systems and processes in place to “rescue” patients when they occur.

- **Rehabilitation:** Though many think the rehabilitative process begins after leaving the hospital, it should begin on the first full hospital day. Patients need to be mobilized early, and physical and occupational therapy consults should be on the admission orders. All patients with even minor head injuries need cognitive testing and evaluation by speech and occupational therapists. Even patients on ventilators in the ICU should be part of an early mobilization program. Data suggest that these early mobilization programs significantly improve long-term outcomes for trauma patients [10]. Any patient with head or spinal cord injuries or with a cluster of serious injuries needs a physical medicine and rehabilitation physician involved with their care early in their hospitalization. The discharge plan needs to be formulated early and the resources of the patient and families need to be understood so the maximum benefit of rehabilitation and recovery can be realized. Many trauma patients are injured while using drugs or alcohol or owing to suicidal or depressive motives. These patients benefit significantly from directed psychiatric or social work interventions regarding their substance abuse issues. All seriously injured patients may suffer from posttraumatic stress. It is the obligation of the trauma service to address these issues and have social services, counselors, and psychiatric services as part of the team so that the patient has the
opportunity for the best possible outcome.

- **Performance improvement:** Providing evidence-based care and striving to provide the best care possible is the mission of every trauma service. Research, education, and injury prevention are all components of that mission. Opportunities for improvement in patient care from specific events or trends in complications must be recognized, dissected, and acted upon to promote quality medical care. Trauma registries serve as a central database for data collection and allow for the evaluation of trends and recognition of areas of improvement. As part of a verified trauma center, this information is shared with the National Trauma Data Bank at the ACS. The information obtained from the trauma center registry feeds an effective PI program. Using the information in the NTDB can identify areas of research and areas where injury prevention can be targeted to reduce traumatic injuries. The knowledge of which injuries are prevalent in that region will direct the focus of the injury prevention program; from helmet or seat belt use to preventing childhood or elderly falls. The wide research activity is encouraged at all trauma centers but is a requirement for Level I centers. Finally, ongoing educational programs of all care givers involved with trauma care, including prehospital and rehabilitative services, is ensured as an essential duty of a trauma center and the trauma system.
Most disasters are major incidents such as plane crashes, explosions in chemical factories, natural disasters such as hurricanes, or results of war, and terrorist activities such as the events of September 11, 2001 or at the Boston Marathon. An effective trauma system should be primed to manage these disasters. To successfully manage a disaster with many victims, there needs to be preplanning and organization of resources. There needs to be training done within the trauma system, stockpiling of supplies, an effective communication and triage system, and a clear understanding of the resources of each hospital and trauma center in the area. Without a trauma system, the wrong facilities would end up with the wrong patients (i.e., a seriously injured patient to a small hospital) or one hospital being overwhelmed while others close by go underused. The trauma system needs to predefine the triage of patients of a disaster according to severity of injury and volume of patients. The most important principle is triage of the most seriously injured to the higher level of care in the fastest amount of time, and to avoid overtriage of minor injuries to the major trauma center. Events such as the Boston Marathon Bombing highlight how an effective regional system allowed for effective care of over 250 injured patients with no in-hospital mortality for the 127 severely injured patients who were cared for at the area’s trauma centers. These unfortunate events highlight the need for disaster planning within trauma systems to be prepared both prehospital and within the hospital in order to deal with the large volume of patients and prevent in-hospital mortality [11,12].
RURAL TRAUMA

The establishment of a trauma system in a rural environment is a unique challenge but important nonetheless to improve outcomes of the injured patients. Most of the problems with rural trauma relate to the time to definitive care at a trauma center. Studies have shown that rural trauma has a higher rate or mortality than urban trauma, but that those who reach definitive care often have similar outcomes. However, because of the rural environment, there is increased discovery time, time for the prehospital personnel to get to the patient, transportation over great distances, and hard terrain. Transfer to the highest level of medical center may take hours or even days depending on how remote an area may be. To decrease the mortality and morbidity of these patients, the trauma system needs to be firmly established; as also, there is a need to designate and train lower-level trauma centers in areas of sparse population, provide consistent training of the volunteer prehospital personnel, and establish effective communication and transport systems between the prehospital care givers and major trauma centers. The American College of Surgeons sponsors specific courses for training in both rural trauma and disaster management—the Rural Trauma Team Development Course (RTTDC) and the Disaster Management and Emergency Preparedness course (DMEP).

In summary, trauma systems provide for early recognition, prehospital care, resuscitation, and operative care, critical care management, long-term care, and rehabilitation. Performance improvement remains an essential trauma system function.
1. Ten Leading Causes of Death by Age Group, United States 2013 (Chart): Center for Disease Control and Prevention.
Sepsis is among the most common reasons for admission to ICUs throughout the world. An epidemiologic study in European ICUs demonstrated a prevalence of 37% for sepsis and 30% for severe sepsis [1]. The incidence of severe sepsis in the United States is estimated to be about 300 cases per 100,000 population [2–4]. Sepsis is reported to be more common in men and among non-White persons [3]. Surgical patients account for nearly one-third of sepsis cases in the United States; this is important as the management of “surgical” and “medical sepsis” differs somewhat. Patients who have had a septic episode are at an increased risk of death for up to 5 years following the acute event [5]. Data from 2004 to 2009 demonstrate a 13% average annual increase in the incidence of severe sepsis with a decrease in in-hospital mortality from 35% to 26% [2]. This study estimated that there were 229,044 deaths from severe sepsis in 2009, which would place severe sepsis as the third most common cause of death in the United States, after heart disease and malignant neoplasms [2]. However, several factors including international classification of disease (ICD) coding rules, the use of administrative data sets, and increased awareness and surveillance confound the interpretation of these epidemiologic data [6,7]. In 1987, the Australian and New Zealand Intensive Care Society (ANZICS) developed a high-quality database that prospectively collects data from all patients admitted to 171 ICUs in Australia and New Zealand [8]. An analysis of this database demonstrates a linear decrease in absolute mortality for severe sepsis and septic shock from 35% in 2000 to 16.7% in 2012, with an annual rate of absolute decrease of 1.3% [9]. It should be noted that the Surviving Sepsis Campaign was not endorsed by ANZICS and was poorly adopted in these two countries [10]. While it has been claimed that the Surviving Sepsis Campaign has contributed to the decline in mortality from sepsis around the world [11,12], this is clearly not the case for Australia and New Zealand. Furthermore, the decline in mortality from severe sepsis and septic shock in the United States was evident long before the “adoption” of the Surviving Sepsis Campaign [3].
It is likely that the earlier recognition and treatment of sepsis as well as advances in ICU care (lung-protective ventilation, conservative blood strategy, etc) are largely responsible for the improved outcomes of patients with sepsis. This chapter will provide an overview of sepsis with particular emphasis on the diagnosis and management of severe sepsis and septic shock.

DEFINITIONS

The word “sepsis” is derived from the ancient Greek word for rotten flesh and putrefaction. Since then, a wide variety of definitions have been applied to sepsis, including sepsis syndrome, severe sepsis, bacteremia, septicemia, and septic shock. In 1991, the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) developed a new set of terms and definitions to define sepsis in a more “precise manner” [13]. These definitions took into account the findings that sepsis may result from a multitude of infectious agents and microbial mediators and may not be associated with detectable bloodstream infection. The term “systemic inflammatory response syndrome” (SIRS) was coined to describe the common systemic response to a wide variety of insults. Four SIRS criteria were defined, namely tachycardia (heart rate >90 beats per minute), tachypnea (respiratory rate >20 breaths per minute), fever or hypothermia (temperature >38°C or less than 36°C), and leukocytosis, leukopenia, or bandemia (WBC >1,200 per µL, <4,000 per µL or bandemia ≥10%). Patients who met two or more of these criteria fulfilled the definition of SIRS. When SIRS was the result of a suspected or confirmed infectious process, patients were defined as having “sepsis.” Severe sepsis was defined as sepsis plus organ dysfunction. Septic shock was a subset of severe sepsis and was defined as “sepsis-induced hypotension persisting despite adequate fluid resuscitation.” However, it became evident that the use of the SIRS criteria to define sepsis was problematic, as it lacked both sensitivity and specificity [14]. Kaukonen et al. [15] evaluated the presence of the SIRS criteria in 109,603 patients with infection and organ failure. In this study, 12% of patients were classified as SIRS-negative sepsis (i.e., had <2 SIRS criteria). Conversely, when the SIRS criteria are applied to an unselected cohort of patients, many patients who do not have an infection are diagnosed as having sepsis [16]. In order to “improve” on these definitions, updated definitions for sepsis and septic shock were released in 2016 by the Third International Consensus Taskforce (Sepsis-3) [17–19]. Sepsis was defined as life-threatening organ dysfunction caused by a dysregulated host response to infection. For clinical operationalization, organ dysfunction was defined as an increase in the
Sequential Sepsis Organ Assessment (SOFA) score of 2 or more points for patients in the ICU. A new bedside score termed quickSOFA (qSOFA) was developed to describe organ dysfunction in non-ICU patients. Patients required at least two of the following qSOFA criteria to be diagnosed as having sepsis: respiratory rate of 22 per minute or greater, altered mentation, or a systolic blood pressure of 100 mm Hg or less. Septic shock was defined as a subset of sepsis with “profound circulatory, cellular, and metabolic abnormalities.” Patients with septic shock are identified by the requirement for vasopressors to maintain a mean arterial pressure of 65 mm Hg or greater and a serum lactate greater than 2 mmol per L in the “absence of hypovolemia.” With the new definitions, the “SIRS criteria” are no longer used to screen for or diagnose sepsis and the term “severe sepsis” was removed. Only time will tell how much of an advance these new criteria provide our patients.
PATHOGENS AND SITES OF INFECTION

Sepsis studies conducted over the past two decades indicate that the lung (pneumonia) is the commonest site of infection, accounting for about 50% of cases, followed by abdominal/pelvic infection (25%), primary bacteremia (15%), urosepsis (10%), and blood stream infections related to vascular access devices (5%). Approximately 25% of patients with severe sepsis are infected with a gram-positive organism, 25% gram-negative organisms, 20% a mixed infection (gram-positive and gram-negative), with anaerobic and fungal infections occurring in less than 5% of cases. Viral pathogens are rare causes of sepsis (Ebola and H1N1 influenzae infections). Despite exhaustive microbiologic tests, a pathogen is not isolated in about 25% of patients. A recent study in patients with community-acquired pneumonia isolated a bacterial pathogen in only 14% of patients [20]. The spectrum of pathogens depends upon the site of infection and whether the patient is at risk of infection with drug-resistant pathogen (see below).
Sepsis is probably the most complex disease known to man. The pathogenetic mechanisms and physiologic changes associated with sepsis are exceedingly complex, with our understanding of this topic rapidly evolving; the reader is referred to excellent reviews on this topic [21–26]. Exposure of human macrophages to bacterial antigens has been demonstrated to result in a significant change in the expression of over 950 genes [27]. These include genes for pro- and anti-inflammatory cytokines, chemokines, adhesion molecules, transcription factors, enzymes, clotting factors, stress proteins, and antiapoptotic molecules. These gene products alter the function of nearly every cell and tissue in the body. Furthermore, these mediators interact in complex positive and negative feedback loops and result in epigenetic modifications that further alter the expression of this network of mediators [25]. The early phase of sepsis is generally believed to result from the uncontrolled production of proinflammatory mediators, the so-called cytokine storm [21,22]. Sir William Osler was the first to recognize that “except on few occasions, the patient appears to die from the body’s response to infection rather than from the infection” [28]. However, recent data suggest that both a proinflammatory and an opposing anti-inflammatory response occur concurrently in patients with sepsis [23,24,29]. In general, following a variable time course, patients transition from a predominantly proinflammatory to an anti-inflammatory immunosuppressive state [23,25,30]. Among elderly patients, particularly those with significant comorbidities, the anti-inflammatory response may predominate [23]. Similarly, surgical and trauma patients who become infected transition rapidly to a predominantly anti-inflammatory response [31].

The cardiovascular changes associated with severe sepsis play a central role in the early management of sepsis and will be briefly reviewed. The major cardiovascular changes in patients with severe sepsis and septic shock include vasoplegic shock, myocardial dysfunction, altered microvascular flow, and a diffuse endothelial injury [32,33]. Sepsis is characterized by increased expression and activation of endothelial adhesion molecules with adhesion and activation of platelets, leukocytes, and mononuclear cells and activation of the coagulation cascade [34]. This results in a diffuse endothelial injury, microvascular thrombosis, gaps between the endothelial cells (paracellular leak), and shedding of the endothelial glycocalyx [35,36]. The combination of these mechanisms contributes to a reduction of functional capillary density, heterogenous abnormalities in microcirculatory blood flow, and increased capillary
permeability [37,38].

Asoplegic shock, due to failure of the vascular smooth muscle to constrict, results in arterial and veno-dilatation [32]. Vasoplegic shock is believed to result from increased expression of inducible nitric oxide synthetase with increased production of nitric oxide (NO), activation of $K_{\text{ATP}}$ channels resulting in hyperpolarization of the muscle cell membrane, increased production of natriuretic peptides (which act synergistically with NO), and a relative vasopressin deficiency [32]. Veno-dilatation increases the size of the nonstressed blood volume decreasing venous return which compounds the intravascular volume deficit caused by the vascular leak.

Myocardial depression of patients with septic shock was first described in 1984 by Parker et al. [39] using radionuclide cineangiography. In a series of 20 patients, these investigators reported a 50% incidence of left ventricular (LV) systolic dysfunction. Notably, in this study, the initial ejection fraction and ventricular volumes were normal among nonsurvivors, and these indices did not change during serial studies; it is likely that these patients had significant diastolic dysfunction. The initial studies evaluating cardiac function for sepsis focused on LV systolic function. However, LV diastolic dysfunction has emerged as a common finding among patients with severe sepsis and septic shock [40]. Adequate filling during diastole is a crucial component of effective ventricular pump function. Diastolic dysfunction refers to the presence of an abnormal left ventricular diastolic distensibility, filling, or relaxation, regardless of LV ejection fraction. Predominant diastolic dysfunction appears to be at least twice as common as systolic dysfunction in patients with sepsis [40]. The largest study to date ($n = 262$), by Landesberg et al. [41], reported diastolic dysfunction for 40% of patients with sepsis, whereas 9.1% of patients had isolated systolic dysfunction. Unlike systolic LV dysfunction, diastolic dysfunction is an important prognostic marker for patients with sepsis [40–42]. Patients with diastolic dysfunction respond very poorly to fluid loading [41]. For these patients, fluid loading will increase cardiac filling pressures and increase venous and pulmonary hydrostatic pressures with the increased release of natriuretic peptides with minimal (if any) increase in SV [43].
